This book is a collective effort involving hundreds of technical specialists. It brings together a wealth of information from worldwide sources to help scientists, engineers, and technicians solve current and long-range problems.

Great care is taken in the compilation and production of this Volume, but it should be made clear that NO WARRANTIES, EXPRESS OR IMPLIED, INCLUDING, WITHOUT LIMITATION, WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE, ARE GIVEN IN CONNECTION WITH THIS PUBLICATION. Although this information is believed to be accurate by ASM, ASM cannot guarantee that favorable results will be obtained from the use of this publication alone. This publication is intended for use by persons having technical skill, at their sole discretion and risk. Since the conditions of product or material use are outside of ASM's control, ASM assumes no liability or obligation in connection with any use of this information. No claim of any kind, whether as to products or information in this publication, and whether or not based on negligence, shall be greater in amount than the purchase price of this product or publication in respect of which damages are claimed. THE REMEDY HEREBY PROVIDED SHALL BE THE EXCLUSIVE AND SOLE REMEDY OF BUYER, AND IN NO EVENT SHALL EITHER PARTY BE LIABLE FOR SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES WHETHER OR NOT CAUSED BY OR RESULTING FROM THE NEGLIGENCE OF SUCH PARTY. As with any material, evaluation of the material under end-use conditions prior to specification is essential. Therefore, specific testing under actual conditions is recommended.

Nothing contained in this book shall be construed as a grant of any right of manufacture, sale, use, or reproduction, in connection with any method, process, apparatus, product, composition, or system, whether or not covered by letters patent, copyright, or trademark, and nothing contained in this book shall be construed as a defense against any alleged infringement of letters patent, copyright, or trademark, or as a defense against liability for such infringement.

Comments, criticisms, and suggestions are invited, and should be forwarded to ASM International.

# Foreword

---

*ASM Handbook* Volume 14B on sheet forming is the second of two volumes on metalworking technology, following the publication of Volume 14A on forging and bulk forming in 2005. These two volumes reflect the continuing mission of the *ASM Handbook*<sup>®</sup> series to provide in-depth and practical engineering knowledge in areas of technological significance.

Like many major manufacturing operations, the technology of sheet-metal fabrication is being transformed in response to the competitive demands of a global economy and computer-aided engineering. Product and process design are becoming more integrated, and all stages of processing are being enhanced by computer technologies that help implement process-control strategies to reduce scrap and achieve net-shape forming capability on the shop floor. These advances involve the efforts of various technical communities, and ASM International is pleased to help disseminate their knowledge for the benefit of others in the economical manufacturing of effective products.

Thanks are extended to all the contributors and especially to Lee Semiatin, who, as Volume Editor, has championed this entire effort with his tireless devotion. Dr. Semiatin is to be congratulated and lauded for all his efforts in identifying and recruiting authors, directing the editorial activities of review and revision, and responding effectively in the development of both Volume 14A and 14B. His volunteer commitment is enormous, and we are indebted to Lee Semiatin.

# Preface

---

Since the 1988 publication of Volume 14, *Forming and Forging* (of the 9th Edition *Metals Handbook* series, subsequently renamed the *ASM Handbook* series in 1991), advances in the forming of sheet metals have focused on a number of new or improved processes, new materials, increasing utilization of flexible-manufacturing and rapid-prototyping techniques, and the application of sophisticated process models and process-control strategies. A number of these advances have been driven by the needs of mass production in the automotive industry, but also partly by niche markets such as aerospace. Inexpensive yet powerful, computing resources have emerged as an important element in process design and control, tooling development, and product-process integration.

Innumerable configurations can be produced from sheet by various fabrication operations such as bending, stretching, deep drawing, hole-making, and flanging. These distinct manufacturing processes are performed in various combinations to produce a finished part along with considerations for material savings and manufacturing ease. Currently, improvements in computational capability are having a significant impact on the cost-effective application, *integrated* engineering evaluation, and robust production of sheet-metal products. The increasing utilization of process-control strategies to reduce scrap and achieve net-shape forming capability during all stages of processing is also enhanced by computer technologies implemented on the shop floor.

This Volume provides a broad overview of sheet-metal fabrication technologies and applications. The intent is to cover basic concepts and methods of sheet forming and developments in forming technology. Since the late 1980s, a number of processes have been introduced and/or undergone substantial improvement. These processes include high-production superplastic forming of aluminum, the use of tailor-welded blanks in automotive manufacturing, increasing utilization of rubber-pad (hydro-) forming, and high-velocity metal forming. Recent advances in the forming of sheet metals also include increasing utilization of flexible-manufacturing and rapid-prototyping techniques. New advances are also being made in the forming of advanced high-strength steels and magnesium alloys. In addition, the evaluation and analysis of material formability is improving with new techniques, such as stress-based forming-limit criteria.

It is hoped that this publication provides a useful reference for the many practitioners in this vital industry. Many thanks go to the contributors, who volunteered their time and expertise in this endeavor. This work would not have been possible without them.

S.L. Semiatin  
Volume Editor

# Contents

<b>Introduction .....</b>	<b>1</b>	Principle of Shape Correction .....	48
Introduction to Sheet-Forming Processes		Shape Corrections .....	49
<i>S.L. Semiatin</i> .....	3	Slitting .....	50
Historical Perspective .....	3	Cut-to-Length Lines .....	54
Classification of Sheet-Forming Processes .....	3	Selection of Materials for Shearing, Blanking, and Piercing	
Process-Related Developments .....	4	Tools .....	57
Rapid Prototyping and Flexible Manufacturing		Shearing Process .....	57
Techniques .....	6	Wear .....	57
Materials-Related Developments .....	7	Wear Control .....	58
Process Simulation, Design, and Control .....	8	Shear-Blade Tool Steels .....	61
Future Outlook .....	9	Materials for Machine Knives .....	63
Design for Sheet Forming		Selection of Material for Blanking and Piercing Dies .....	65
<i>Howard Kuhn</i> .....	11	Trimming Operations .....	69
Hole Punching .....	11	Analysis of Parts to be Trimmed .....	69
Flanging .....	12	Selection of Trimming Dies .....	69
Beads and Ribs .....	14	Rough and Finish Trimming .....	71
Large Recesses .....	14	Construction Details of Trimming Dies .....	71
Scrap Reduction .....	18	Selection of Presses for Trimming .....	72
<b>Shearing, Cutting, Blanking, and Piercing .....</b>	<b>21</b>	Scrap Handling .....	72
Cutting Operations .....	23	Material Handling in Trimming .....	72
Mechanical Methods of Cutting .....	23	Combined Operations .....	73
Gas Cutting .....	24	<b>Other Cutting Methods</b>	
Electric Arc Cutting .....	25	Oxyfuel Gas Cutting .....	74
Laser Cutting .....	26	Principles of Operation .....	74
Abrasive Waterjet Cutting .....	26	Process Capabilities .....	74
Principles of Shearing, Blanking, and Piercing .....	28	Properties of Fuel Gases .....	75
Shear Action in Metalcutting .....	28	Fuel Types .....	76
Deformation .....	29	Effect of Oxyfuel Cutting on Base Metal .....	79
Penetration .....	29	Equipment .....	81
Clearance .....	29	Starting the Cut .....	84
Stripping Force .....	30	Light Cutting .....	84
Shearing Force .....	30	Medium Cutting .....	85
Diameter-to-Thickness Ratios .....	33	Heavy Cutting .....	85
Limitations of Punching .....	33	Stack Cutting .....	86
Die Clearances and Stripping Forces .....	33	Preparation of Weld Edges .....	87
Shearing of Sheet, Strip, and Plate		Applicable Shapes .....	88
<i>L. Chen</i> .....	39	Gas Cutting versus Alternate Methods .....	90
Straight-Knife Shearing .....	39	Close-Tolerance Cutting .....	91
Rotary Shearing .....	43	Oxyfuel Gouging .....	91
Safety .....	44	Other Gas Cutting Methods .....	92
Flattening, Leveling, Slitting, and Shearing of Coiled Product		Safety .....	95
<i>L. Chen</i> .....	46	Electric Arc Cutting .....	96
Flattening and Leveling .....	46	Plasma Arc Cutting .....	96

# Introduction to Sheet-Forming Processes

S.L. Semiatin, Air Force Research Laboratory

---

SHEET FORMING comprises deformation processes in which a metal blank is shaped by tools or dies, primarily under the action of tensile stresses. The design and control of such processes depend on the characteristics of the workpiece material, the conditions at the tool/workpiece interface, the mechanics of plastic deformation (metal flow), the equipment used, and the finished-product requirements. These factors influence the selection of tool geometry and material as well as processing conditions (workpiece and tooling temperatures, lubrication, etc.). Because of the complexity of many sheet-forming operations, models of various types, such as analytic, physical, or numerical models, are often relied on to design such processes.

This Volume presents the state of the art in sheet-forming processes. A companion volume (Volume 14A, *Metalworking: Bulk Forming*, 2005) describes the state of the art in bulk-forming processes. Various major sections of this Volume deal with descriptions of specific processes, selection of equipment and die materials, forming practice for specific alloys, and various aspects of process design and control. This article provides a brief historical perspective, a classification of sheet-forming processes, and a summary of some of the more recent developments in the field. Since the publication in 1988 of the last edition of *ASM Handbook* Volume 14, *Forming and Forging*, sheet-forming practice has seen a number of notable advances. Recent materials developments include the introduction or increased application of advanced high-strength steels, magnesium alloys, and superplastic sheet materials. New or improved process developments include application of flexible manufacturing and rapid prototyping techniques and the increased use of sophisticated process simulation and control tools. Some of these technological advances are briefly summarized in this article.

## Historical Perspective

Bulk-forming techniques such as forging have been used in various forms for thousands of years. By comparison, sheet-forming processes, except for the bending of narrow workpieces, are relatively recent. This is because techniques to

roll wide sheets of metal of uniform thickness were not developed until the 1500s. It was not until the middle part of the 19th century, however, that mass production via sheet forming became a reality with the advent of processes for forming tin-plated sheet steels for the canning industry (Ref 1). Subsequently, two major commercial sectors set the pace for advances in sheet forming, namely, the automotive industry, beginning at approximately the turn of the 20th century, and the home-appliance industry after World War I. Both of these industries required large quantities of low-carbon sheet steel. Such needs were met by the development of tandem-mill rolling, a technology pioneered in the paper industry and subsequently adopted in the steel industry by the American Rolling Mill Company (Armco) and others.

During the latter half of the 20th century, the need to reduce the weight of automobiles to improve fuel economy spurred the development of various grades of high-strength sheet steels in addition to low-carbon and ultralow-carbon steels with improved formability. These developments were aided by increased knowledge of the effect of alloying, rolling, and annealing practices on ductility, plastic anisotropy, and thus stamping performance as well as on post-formed properties. The transition from glass (primarily used prior to the 1970s) to metallic containers for beverages also led to a boom in the sheet-metal rolling and forming industries, first for steel and then for aluminum.

More recently, warm and superplastic forming techniques for aluminum and magnesium sheet alloys have been developed and implemented in the automotive and other industries. Furthermore, the conventional and superplastic forming of titanium, nickel-base, and refractory alloys has become commonplace for aerospace applications. These developments have been aided by increased knowledge related to formability, the effect of prior processing on microstructure and texture evolution in sheet materials, and the constitutive response of metals during forming. The development of powerful user-friendly finite-element codes for process simulation and design, the advent of rapid prototyping applications, the adoption of flexible binder technology, and the use of adaptive process controls have been among the most recent advances in the area of sheet forming.

## Classification of Sheet-Forming Processes

In metalworking, an initially simple part—a billet or a blanked sheet, for example—is plastically deformed between tools (or dies) to obtain the desired final configuration. Metal-forming processes are usually classified according to two broad categories:

- Bulk, or massive, forming operations
- Sheet-forming operations

Sheet forming is also referred to as forming. In the broadest and most accepted sense, however, the term *forming* can be used to describe both bulk-deformation processes and sheet-forming processes. Forming processes are also typically classified further into categories, as described in Fig. 1.

In both bulk and sheet deformation, forming is done with some contact between the surfaces of the deforming metal and a tool. Depending on the nature of the contact, friction between the tool and workpiece also may have a major influence on material flow. The major distinction is that deformation occurs in bulk or in a more localized or directional fashion. Bulk-forming operations typically involve multidirectional deformation throughout the volume of a worked mass, as in the cases of forging, extrusion drawing, rolling, coining, sizing, and thread forming. In bulk forming, the input material is in billet, rod, or slab form, and the surface-to-volume ratio in the formed part increases considerably under the action of largely compressive loading. Bulk-forming processes are described in *Metalworking: Bulk Forming*, Volume 14A of *ASM Handbook*, 2005.

In contrast to bulk forming, sheet forming often involves local deformation. During sheet forming, a piece of sheet metal is plastically deformed by tensile loads into a three-dimensional shape, often without a significant change in its thickness or surface characteristics. The characteristics of sheet-metal-forming processes are (Ref 3):

- The workpiece is a sheet or a part fabricated from a sheet.
- The deformation usually causes significant changes in the shape, but not necessarily the cross-sectional area, of the sheet.

## 4 / Introduction

- In some cases, the magnitudes of the plastic and the elastic (recoverable) deformations are comparable; therefore, elastic recovery or springback may be significant.

Examples of sheet-forming processes include deep drawing, stretching, bending, rubber-pad forming, and other methods (Fig. 2). Sheet-forming methods can also be classified according

to suitable methods in obtaining desired dimensional features, such as surface contours or deep recesses (Table 1). Some methods of local deformation also extend beyond sheet forming to the bending and forming of solid sections and tubular products. These forming methods are discussed in the Section “Forming of Bar, Tube, and Wire” in this Volume.

## Process-Related Developments

During the last decade, a number of processes have been introduced and/or undergone substantial improvement. These processes include high-production superplastic forming of aluminum, the forming of tailor-welded blanks, rubber-pad (hydro) forming, and high-velocity metal forming.

**Superplastic forming (SPF) of aluminum** has recently been commissioned for high-production applications in the automotive industry. Unlike previous niche applications of the technology, in which forming rates were very slow ( $\sim 10^{-4}$  to  $10^{-3}$  s $^{-1}$ ) and workpiece temperatures were relatively high ( $\sim 500$  °C, or 930 °F), newer uses of aluminum SPF comprise moderate strain rates ( $10^{-3}$  to  $10^{-2}$  s $^{-1}$ ) and somewhat lower temperatures. Perhaps the largest-volume use of the new approaches is that recently introduced by General Motors for the forming of 5083 aluminum-magnesium alloy sheet and referred to as quick plastic forming (QPF) (Ref 5, 6). As in other SPF techniques, SPF shaping usually involves the blow forming of prelubricated panels into a female die. Typical forming times are of the order of 5 min, or a fraction of the time used for more conventional SPF of aluminum (and titanium) sheet-metal parts. The QPF manufacturing cell (Fig. 3) uses sheet that has been preblanked and coated with boron nitride to enhance separation of finished parts from the tooling following forming. Using primarily robotic means for improved safety and control, blanked sheets are then passed through successive stages comprising convection oven preheating outside the press, forming, cooling, and transfer from the cell to subsequent operations. Dimensional and distortion control are enhanced by the use of tool-based extraction of parts following forming and the prevention of lubricant buildup by cleaning the hot tooling using dry ice. An additional important design enhancement comprises the use of specially designed heated tooling rather than a more conventional system in which the entire die set/die stack is heated.

Additional information on superplastic forming is contained in the article “Superplastic Sheet Forming” in this Volume.

**Forming of tailor-welded blanks** is a technology that was first used in the 1980s but received substantial attention only in the last 5 to 10 years. Most tailored blanks consist of steels of different thicknesses, grades/strengths, and sometimes coatings that are welded prior to forming (Ref 7). Welding processes include

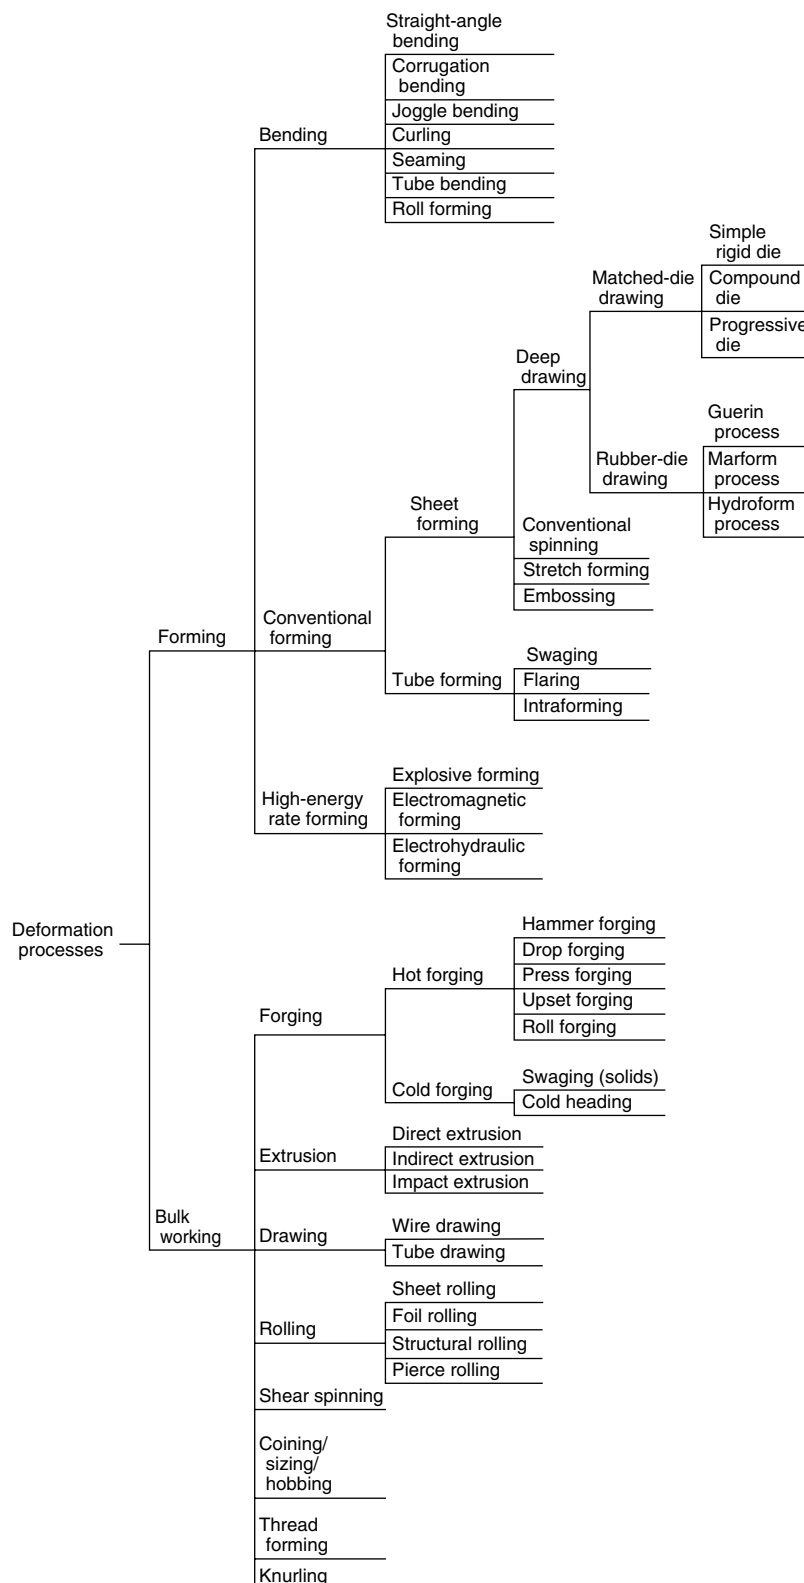

Fig. 1 Taxonomy of deformation processes. Source: Ref 2

seam, high-frequency butt, friction, and laser welding techniques. Finished parts with a desirable variation in properties are thus produced. For example, specific areas of a structure requiring higher strength or load-carrying capability may use steel of a thicker gage or different composition; other areas may require a steel with higher corrosion resistance. Employed primarily by the automotive industry, the approach can yield property blends that can lead to substantial vehicle weight savings and thus improved fuel economy. Other applications

have been proposed in the construction industry; these include prefabricated building panels, steel decking, and highway crash barriers. Manufacturing issues relate to the forming characteristics of tailor-welded blanks, the ability to hold dimensional tolerances, and the aesthetics of the weld for parts in which the joint is exposed. For instance, even when blanks are joined using laser welding, the seam is still usually visible after painting. Therefore, tailor-welded-blank applications in the automotive industry tend to be restricted to nonvisible areas or locations in

which body moldings can be used to cover the seam. More information in this area can be found in the article “Forming of Steel Tailor-Welded Blanks” in this Volume.

**Rubber-pad (hydro) forming** in its simplest form comprises the forming of sheet metal using (1) a flexible rubber pad and rigid punch around which the sheet is shaped, or (2) a die into which the sheet is formed under the action of a pressurized fluid acting on a rubber diaphragm. Thus, tooling costs are considerably reduced because a number of different part geometries can be made using the same pad/fluid medium. In addition, the process often provides better dimensional control, less springback, and the capability of producing parts with greater complexity or using fewer forming steps. In the 1980s, rubber-pad forming of sheet metals was primarily applied to make automotive and aircraft skin panels that required limited production runs for which the cost of conventional hard tooling was difficult to justify. More recently, various process modifications, such as warm hydroforming, integral hydrobulge forming, combined drawing and bulging, and viscous pressure forming, have been introduced (Ref 8). In addition, methods for enhancing flange draw-in, such as the introduction of fluid pressure against the edge of the blank, have been reported to lead to significant increases in drawability during hydroforming. More information on this technology is summarized in the article “Rubber-Pad Forming and Hydroforming” in this Volume.

**High-velocity metal forming (HVMF)** consists of those processes in which high-strain-rate

impulsive loading is used to deform sheet metal into the shape of a die into which it is accelerated. The advantages of HVMF relative to conventional sheet-forming processes include improved formability and reduced wrinkling, more uniform strain distribution in a single forming step, reduced springback, and the ability to impart fine details over large areas. Including techniques such as explosive, electromagnetic, and electrohydraulic forming, these methods have been used for some time, primarily for very specialized applications with small lot sizes. Although the main features of modern HVMF equipment were well established in the 1960s and 1970s, the increased potential of HVMF via its incorporation into hybrid systems has been realized only during the last few years. Hybrid systems include punch-and-die or hydroforming setups in which an HVMF subsystem has been embedded into the tooling. In so doing, forming operations that would typically require multiple forming steps and sets of dies can be accomplished in a single, modified set of tooling. For example, Ref 9 describes how electromagnetic forming (EMF) coils can be inserted into conventional tooling to aid in forming sharp-corner radii or other fine features that require the improved formability that HVMF provides (Fig. 4); typically, the EMF impulse is applied near the end of the forming process in such cases. As a demonstration, hybrid hard tooling/EMF forming has been applied to the manufacture of an aluminum inner door panel, a part that could not be fabricated using traditional methods (Ref 10). In this case, the electromagnetic actuator was used to put a sharp corner into the sheet to which a large radius of curvature had been imparted by conventional stamping. Another hybrid approach based on combining hydroforming and electrohydraulic or explosive forming has also been proposed. In this case, the press tonnage required to develop the high fluid pressures needed to ensure the flow of the sheet into fine details at the end of forming is reduced by using local HVMF. More information on HVMF is contained in the article "High-Velocity Metal Forming" in this Volume.

## Rapid Prototyping and Flexible Manufacturing Techniques

These include cost-effective approaches to evaluate tooling designs prior to the manufacture of expensive steel dies and dieless forming techniques such as thermal forming and peen forming. Additional information in this area is contained in the articles "Rapid Prototyping for Sheet-Metal Forming," "Thermal Forming of Sheet and Plate," and "Peen Forming" in this Volume.

**Rapid prototyping (RP)** in the sheet-forming industry most commonly involves the fabrication of dies from inexpensive materials in order to evaluate metal flow and possible defect generation (e.g., excessive thinning, wrinkling, etc.) prior to the sinking of steel dies. Rapid prototyping dies are an economical alternative for making parts when lot sizes are relatively small. Techniques for making RP dies include stereolithography, laminated object manufacture, and fused deposition processes. These techniques are similar in that they make use of a computer-aided design file to produce an object, such as a die, in a layer-by-layer fashion. For example, in a typical stereolithography approach, an ultraviolet source selectively scans the surface of a liquid (light-sensitive) photopolymer resin in order to cure the desired pattern describing the die cross section. The substrate is then lowered a small amount (typically  $\sim 0.1$  to  $0.5$  mm, or  $0.004$  to  $0.02$  in.). The process is then repeated to produce the next and subsequent layers in a similar fashion. Using this technique, a die can typically be made in several hours, which is very short in comparison to the time for making the corresponding steel die ( $\sim 50$  to  $100$  h). Furthermore, dies made by this means can produce a modest number ( $\sim 3$  to  $30$ ) of sheet-metal parts from aluminum alloys, mild steel, and stainless steel using both conventional and hydroforming presses (Ref 11).

**Thermal forming** is a dieless, flexible manufacturing technique for forming sheet metals. It consists of the local heating of sheet using

laser, plasma, or other sources to effect controlled shapes. The mechanism underlying thermal forming is the development and control of temperature gradients both through the thickness and across the plane of the sheet. These gradients produce local stresses that primarily cause bending and, to a lesser extent, upsetting and buckling (Ref 12). Such forming approaches are best suited for making parts in small quantities or to evaluate the form and fit of a new part. Thus, thermal forming can also be classified as an emerging RP technology. Originally used in the 1980s for the forming of plate, the method has been explored for the forming of sheet since the 1990s. Initial work used lasers as the heating source. Because of the expense, low energy-conversion efficiency, and safety concerns (due to multidirectional reflections of the laser beam), among other factors associated with laser-based systems, the use of other heating methods, such as plasma-arc sources, is currently being examined. The design of one plasma-arc apparatus (Ref 13), for instance, comprises four components: a plasma-arc torch, a positioning system, a cooling system, and control software (Fig. 5a). The principal control variables include the torch power, the heating trajectory along the sheet surface, the tilt angle between the torch and the workpiece, and the torch stand-off distance. Figure 5(b) illustrates the forming of a stainless steel box using a plasma-based system.

**Peen forming** is another dieless, flexible manufacturing technique for forming sheet metals. It is used to make large plan-area parts that are produced in small lot sizes, primarily for the aerospace and ship building industries. Forming relies on the deformation imparted by the impact of balls, which replace conventional forming dies. Unlike shot peening, in which deformation is usually limited to very shallow depths ( $\sim 100$  to  $200$   $\mu\text{m}$ , or  $4$  to  $8$  mils) in a bulk workpiece, peen forming introduces plastic deformation to depths that correspond to a large portion of or the entire cross section of a sheet. At modest shot velocities, only the surface layers are elongated, resulting in a convex curvature of the sheet (Fig. 6). At higher shot velocities, the

Fig. 4 Tooling designs for hybrid systems combining conventional tooling and electromagnetic forming. (a) General setup. (b) Closeup in one section. Source: Ref 9

entire cross section is deformed; the deformation is highest on the surface opposite to the impact surface, and, in these instances, a concave curvature is developed in the sheet. Although peen forming was originally developed and applied in the 1950s for simple shapes, a number of major advances and new applications have recently been made. These include double-sided, simultaneous peen forming, which enables the formation of curvatures that are either more complex or with considerably smaller radii (Ref 15). The technique has also been applied to straighten laser-welded stringer reinforcements in aircraft fuselages (Ref 16).

**Dieless numerical-control (NC) forming** is yet another dieless flexible manufacturing technique for making sheet-metal parts, usually in small lot sizes. The process uses simple tooling to form small, local regions of sheet material in an incremental fashion until the entire part is made. In practice, the geometry of the sheet-metal part is converted from computer-aided design data through a computer-aided manufacturing system to NC data. These data are then downloaded to a three-axis computer numerical-control machine, which drives the forming tooling (Fig. 7). The blank is clamped to a square blankholder (workholder) such that

there is no draw-in from the binder. The so-called *z*-tool moves in the *z* (vertical) and *y* directions; the workholder is counterbalanced to the vertical movement of the *z*-tool and is translated in the vertical direction according to the descent of the *z*-tool and along the *x* and *y* directions. The *x*- and *y*-plane movements are synchronized with the tool motion to produce the desired form on the sheet. Often, a support tool is placed under the workholder, and the sheet-metal blank is formed against it. By this means, the stretching and bending deformations are well controlled.

## Materials-Related Developments

Recent materials developments include the introduction or increased application of advanced high-strength steels, magnesium alloys, and various ultrafine-grain materials for superplastic sheet forming.

**Advanced high-strength steels (AHSS)** are materials that are receiving much attention in the automotive industry as a means to reduce vehicle weight and improve fuel economy. Spurred by initiatives such as the Ultra-Light Steel Auto Body program, the implementation of AHSS is aimed at providing material properties that bridge the range between conventional microalloyed high-strength steel grades (with strengths of 210 to 550 MPa, or 30 to 80 ksi) and ultrahigh-strength steels (with strengths >550 MPa, or 80 ksi), while maintaining adequate sheet formability (Fig. 8). This property combination is due to the higher strain-hardening rates of AHSS, which possess multiphase microstructures of ferrite, martensite, bainite, and/or retained austenite in various

amounts. Specific types of AHSS include dual-phase, transformation-induced plasticity, complex-phase, and martensite grades. The strength of these grades is also enhanced during the bake-hardening cycle following painting. The increase in strength increases with prior forming strain, unlike conventional bake-hardenable grades for which little additional hardening occurs in regions that have undergone strains greater than ~2% during forming. The specific microstructures and mechanical behavior of each of the AHSS is summarized in Ref 17 and in the article "Forming of Advanced High-Strength Steels" in this Volume. Application guidelines are in Ref 18.

**Magnesium alloys** exhibit a relatively high strength-to-density ratio, making them excellent candidates for lightweight structural application, but possess poor formability at room temperature. The low ductility arises from the limited number of slip systems in the hexagonal close-packed crystal structure of magnesium that restrict the ability to accommodate uniform deformation in each grain in a polycrystalline material. At temperatures between approximately 225 and 300 °C (440 and 570 °F), however, additional slip modes become active, and formability increases substantially. Thus, the warm forming of magnesium sheet has recently been developed to make items such as computer cases and, perhaps in the future, automotive parts. The successful application of warm forming requires a careful consideration of the stress-strain behavior of the specific alloy to be used, requirements related to the type of press and press-speed controls, and tooling/heating system design for a high-production environment. These considerations are described in

**Fig. 5** Thermal forming of sheet metals using a plasma-arc heating source. (a) Schematic illustration of the equipment. (b) Stainless steel sheet-metal blank and box that was thermally formed. Source: Ref 13

**Fig. 6** Schematic illustration of the deformation during peen forming that produces a convex sheet curvature. Source: Ref 14

**Fig. 7** Schematic illustration of dieless numerical-control forming. Courtesy of Amino Corporation

detail in the article “Forming of Magnesium Alloys” in this Volume.

**Ultrafine-grain sheet materials** have enabled superplastic sheet forming at lower temperatures and/or higher strain rates than materials with conventional microstructures. Such materials typically contain a submicrocrystalline microstructure produced by severe plastic-deformation techniques such as equal-channel angular extrusion, multiaxial (*abc*) forging, and/or flat rolling, usually at warm working temperatures. For example, warm working of beta-annealed and water-quenched alpha/beta-titanium alloys has been used to develop ultrafine microstructures that can be superplastically formed at a temperature of the order of 775 °C (1425 °F), which is ~100 to 150 °C (180 to 270 °F) lower than typical (Ref 19–21). The lower processing temperature reduces sheet contamination (alpha-case formation), enables the use of less-expensive tool materials, and gives rise to faster cycle times, all of which improve process economics.

**Superalloy sheet materials for superplastic forming** were commercialized in the 1990s. Similar to aluminum and titanium superplastic sheet alloys, these materials have a very fine grain size and moderately high values of the strain-rate sensitivity index (*m* value). One of the materials in this class is the SPF version of alloy 718. This material has been made using conventional hot working followed by a series of cold working and annealing steps to produce sheet with a thickness of 2 mm (0.08 in.) or less (Ref 22). The sheet has a grain size of the order of ASTM 12 (~5 μm, or 0.2 mil), which is stable at SPF temperatures of ~925 to 980 °C (1700 to 1800 °F) and strain rates of  $\sim 10^{-4}$  to  $10^{-3}$  s<sup>-1</sup>. Under these processing conditions, the material

exhibits a tensile ductility of at least 250% and can be used to make parts in 1 to 3 h using a gas pressure of ~2 MPa (0.3 ksi).

## Process Simulation, Design, and Control

Substantial progress in the design and control of sheet-forming processes has been realized since the 1980s. As for bulk forming, much of this progress has been paced by the development and application of powerful computer codes for process simulation.

**Process simulation tools** for sheet forming have been largely finite-element-method (FEM) based, as has been the case for the simulation of bulk-forming processes. However, there are a number of special challenges associated with the application of FEM for sheet forming. These include the selection of element type, the treatment of contact conditions, and the description of the constitutive behavior of the workpiece material (Ref 23). Shell elements that provide information on through-thickness variations of stress and strain have been found to provide the most accurate simulation predictions. The complexity of the variable contact between the workpiece and dies during sheet forming as well as the friction conditions specific to different forming processes also pose a challenge in FEM simulations.

Because the majority of sheet forming is conducted at cold or warm working temperatures using rolled sheet materials with varying degrees of crystallographic texture, the description of constitutive behavior in the FEM code is usually considerably more complex than that for the simulation of hot, bulk-forming operations.

Hence, various internal-state variable models have been found to be useful to describe the evolution of dislocation density, substructure, and strength. In addition, the most accurate simulation results are obtained when texture evolution is simulated simultaneously with deformation and then used to formulate the yield function and flow rule that are important parts of the FEM formulation. The complete simulation of sheet-forming operations in which texture is tracked and updated continuously with strain, however, can be very complex and computationally intensive (Ref 24, 25). Hence, various methods have been used to simplify the problem depending on the precise output that is desired. If detailed information of the final texture is not needed, for example, the most straightforward approach is to use a yield function and flow rule for the starting material that have been derived from a crystal-plasticity analysis, but not update these functions during each increment of deformation. This approach has been applied, for example, to simulate the warm forming of aluminum-magnesium alloys (Ref 26).

Accurate sheet-forming FEM simulations are being used increasingly to establish regions in which undesirably large amounts of thinning or workpiece fracture may occur. In addition, FEM has been used to quantify the local deformation and fracture behavior and hence edge quality produced during the blanking of sheet metal (Ref 27). For instance, FEM predictions in conjunction with the McClintock ductile failure criterion (Ref 28) were used to establish the occurrence of material fracture during the blanking of low-carbon steel.

**Process control technology** represents an increasingly important aspect in sheet forming, especially with regard to controlling dimensional accuracy and avoiding failure. For example, the control of part springback following forming is important with regard to subsequent forming or assembly operations. Springback may be mitigated via changes in the forming process itself or by die design alterations. The former method relies on reducing stress gradients through the sheet thickness (which give rise to bending moments and thus springback) by applying tensions during or following stamping. Specifically, control of the blankholder force may be used during forming, or reverse-bending tooling may be used following forming. In the former case, care is required to avoid deforming the sheet to the point at which localized thinning and tearing may occur, as may be the case for complex or severely drawn parts that are processed close to the forming limit of the workpiece material.

Compensation for springback can also be made via changes in die design such that the desired geometry is achieved following unloading after forming. These approaches typically involve a series of FEM simulations in which tooling, lubrication, and process variables are varied. At the end of each simulation, the values of an objective function (e.g., deviation from

**Fig. 8** Yield strength and formability (in terms of tensile ductility) of conventional high-strength steels (HSS) and advanced high-strength steels (AHSS). Types of steels: BH, bake-hardening; CMn, carbon-manganese; CP, complex phase; DP, dual-phase; HSLA, high-strength, low-alloy steel; IF-HS, interstitial-free high strength; IF, interstitial-free; IS, isotropic steels; MART, martensitic; TRIP, transformation-induced plasticity. Adapted from Ref 17 and 18

desired part shape) and their gradients (i.e., changes with respect to the change in each control parameter) are determined in order to pick a new search direction in control-parameter or die-shape space. Other methods to establish appropriate die designs to compensate for springback (e.g., the so-called springforward and displacement adjustment techniques) have also been investigated. These methods, as well as a detailed discussion of the modeling and control of springback, are discussed in the article "Springback" in this Volume.

**Closed-loop feedback systems and flexible binders** are currently being considered and implemented for the control of sheet-forming processes. In traditional stamping, sheet panels are drawn using rigid binders (blankholders) with constant preset binder forces under open-loop press control. The primary function of the blankholder is to control the amount of metal that flows into the die cavity so that wrinkling, localized thinning, and tearing are avoided. Binders may be flat or contain a drawbead. In flat binders, restraining forces in the drawn sheet are provided by friction between the binder plates and the sheet metal. In fixed drawbead binders, the restraining forces result from a combination of plastic deformation and friction. Variations in material and process variables (lubrication/friction behavior, blank thickness, material behavior, blank placement, die wear) may introduce irregularities that give rise to erratic forming response.

It has been found that failure by wrinkling or tearing is highly dependent on the magnitude and trajectory of the binder force. The dynamic, closed-loop control of one or several process variables, such as the binder force, may be used to compensate for material/process variations and thus help to reduce or eliminate scrap. For example, researchers (Ref 29, 30) have demonstrated the closed-loop approach for the deep drawing of drawing-quality low-carbon steel

cups. It was found that variations in lubrication were the most likely reason for variations in forming performance. The objective of this work, therefore, was to develop a strategy to control the binder force in such a way as to produce a punch-force-versus-stroke trajectory that had been found to produce a sound part in a consistent fashion. Hence, the punch force was used as the control parameter for modulating the binder force during the drawing process.

In related work, the Institute of Metal Forming Technology of the University of Stuttgart in Germany has developed an advanced flexible binder control system with individually controlled hydraulic cylinders (Fig. 9). Cone-shaped segments localize the applied pressure in specific areas without influencing the pressure in adjacent areas. Individual control of local binder areas thus allows precise control of metal flow into the die cavity. Unlike rigid binders, a flexible binder produces the right amount of elastic deformation in the binder area and thus the optimal friction conditions for metal flow. The flexible binder technology has been successfully demonstrated on a full-sized aluminum front fender using both open-loop control and an iterative process for pin-force selection guided by computer simulation. Results from the trials showed that flexible binder technology improves the quality of fenders by allowing the manipulation of pressure settings in binder areas that control metal flow to the locations at which defect formation is most likely. Flexible binder control technology has also been applied for the drawing of double-sided stainless steel sinks (Ref 31).

**Computer-aided engineering (CAE) systems** developed during recent years have incorporated various elements of product design, process design, and process control. Designed primarily for the automotive industry, some of the newer commercial systems allow the design of die faces, binders, and so on for the complete die line, including blank development/blanking, die structural analysis, forming, trimming, flanging, and springback compensation. In some cases, geometrical features, friction, and so on can be entered parametrically to allow optimal overall designs to be determined rapidly via an automated iterative procedure and with less intervention by the process analyst. The analysis of the metal-forming processes themselves have benefited from improved descriptions of material properties (e.g., better yield functions for anisotropic sheet materials) and failure criteria (e.g., the development of stress-based forming-limit criteria). Results from CAE systems can also be used to evaluate the quality of the final product and its suitability for the intended service application. For instance, the variation in local thickness and yield strength (due to strain hardening) in various regions of a part is readily ascertained.

Additional information in the areas of process simulation, design, and control is contained in the articles "Computer-Aided Engineering in Sheet-Metal Forming," "Process Modeling and

Simulation for Sheet Forming of Aluminum Alloys," "CAD/CAM and Die Face Design in Sheet Metal Forming," and "Process and Feedback Control for Manufacturing" in this Volume.

## Future Outlook

Recent advances in the forming of sheet metals have focused on the development of a number of new or improved processes, the increasing use of flexible manufacturing and rapid prototyping techniques, and the application of sophisticated process models and process control strategies. A number of these advances have been driven by the needs of mass production in the automotive industry, but also partly by niche markets such as aerospace. The application of inexpensive yet powerful computing resources has and will continue to be an important element in process design and control. From a design standpoint, computer-aided techniques for tooling and heating system design, tooling manufacture, and overall process design will continue to play a vital role in maintaining the economic viability of the sheet-metal-forming industry in light of the inroads made by various nonmetallic materials. The increasing use of process control strategies to reduce scrap and achieve net shape forming capability during all stages of processing will also be enhanced by computer technologies implemented on the shop floor.

# Design for Sheet Forming

Howard Kuhn, Consultant

MECHANICAL PARTS are designed to meet specific functional requirements, such as transmission of loads (mechanical, thermal, or electromagnetic), geometric connectivity, and filling of space. At the same time, design should attempt to satisfy objectives for sustainability, including ease of manufacture, prolonged reliability, and recyclability. Sheet-forming processes provide considerable geometric and material flexibility in meeting these requirements, and design of parts for sheet forming must take into account these benefits as well as the limitations of the processes.

Production of sheet metal parts starts with flat stock (generally cold-rolled strip). A two-dimensional pattern is cut from the sheet, and then a sequence of unit operations is used to form the pattern into a part (generally three-dimensional). Unit sheet-forming operations include punching, bending, stretching, and drawing and are usually performed with hard tooling, but may include rubber pad tooling in combination with hard tools. These operations are used to form a wide variety of geometric features such as holes, flanges, beads and ribs, bosses, and deep or shallow recesses. Such features can be combined in various ways to meet the design requirements of the part, such as strength and attachment locations for joining with other parts. While meeting the functional design requirements, designers can also exercise options that reduce the amount of material used and/or reduce die maintenance and other manufacturing considerations.

The variety and combination of geometric features that can be produced by sheet forming is virtually endless, and comprehensive examination of the design benefits and limits of each feature is beyond the scope of this article. Reviewing each of the basic forming operations and their general geometric features, however, will illustrate the general approach to design for sheet forming and the considerations that must be made for material savings and manufacturing ease, in addition to part function. The basic operations include hole making, flanging, bead and rib forming, and stretching and drawing for shallow or deep recesses.

## Hole Punching

Holes and slots are used in sheet metal parts for attachment and assembly to other parts or components. In some cases, multiple holes are used for passage of fluids, as in filters and grates. Hole making in sheet metal involves the use of a punch and die to separate a slug from the sheet by shearing. The sequence of localized deformation in hole punching is shown in Fig. 1. After a small amount of plastic indentation by the punch, severe shearing deformation occurs between the punch edge and the die corner. Cracks begin to form within this shear zone at the punch and die corners and then progress toward each other. Final separation of the slug from the sheet involves tearing, resulting in a burr around the exit perimeter of the hole. This same sequence of events occurs in all shearing operations, including blanking of the initial two-dimensional pattern for subsequent forming steps, as well as in trimming excess metal from a formed part.

As a result of the shearing operation in Fig. 1, part of the surface of the hole is burnished (due to pure shear deformation) and part of it is a ragged fracture surface. Such surfaces are not suitable for load bearing or for threading without further processing, but they can be used as clearance holes for fasteners or shafts.

**Hole Flanging.** Holes can be flanged, or collared, to strengthen them and to provide an area for threading, if required. Collaring is accomplished by hole punching and expansion or by piercing and expansion, as shown in Fig. 2(b) and (c). In punching and expansion, a double action punch is used that first punches a small hole and then expands it by passing the tapered section of the punch through the hole. Because of the raggedness of the punched (sheared) edge, expansion of the hole circumference by the tapered die may cause cracking at the edge. The amount of expansion achievable without tearing can be increased by using a punch having a logarithmic profile, called a tractrix (Ref 2). Piercing and expansion (Fig. 2c) accomplishes both hole making and collaring in one continuous stroke but leaves a very ragged hole edge.

**Fig. 1** Shearing deformation during hole punching (a); initial indentation by the punch is followed by intense shearing between the punch and die and then fracture for final separation. These stages are manifest in the appearance and surface finish of the hole (b). Source: Ref 1

**Hole Size.** The size of holes that can be punched is limited by the sheet material strength and thickness. As is evident in Fig. 1, the hole-making punch is subjected to a compressive load, which is equal to the force required to cause the shearing action. The resulting punch stress for a round punch is given by:

$$\sigma = 4\tau T/D \quad (\text{Eq 1})$$

**Fig. 2** Hole making by (a) punching, (b) punching and expansion, and (c) piercing. Source: Ref 1

**Fig. 3** Hole punching parameters. (a) Allowable sheet thickness-to-punch diameter for hole punching as a function of material shear strength. (b) Minimum punch diameter (hole size) as a function of material thickness for three materials: A, 195 MPa (28 ksi) copper; B, 345 MPa (50 ksi) steel; C, 690 MPa (100 ksi) heat treated steel. Note that, for a given sheet thickness, the minimum allowable hole diameter increases as the material strength increases.  $T$ , thickness;  $D$ , diameter. Source: Ref 1

where  $\sigma$  is the compressive stress in the punch,  $\tau$  is the shear strength of the sheet metal,  $T$  is the sheet thickness, and  $D$  is the punch diameter. For a given punch material, the allowable  $T/D$  ratio is inversely proportional to the shear strength of the sheet material, so the minimum hole diameter that can be punched increases with increasing strength of the sheet material (Fig. 3).

A further constraint on punch diameter is imposed by the buckling failure mode. Taking the punch length to be at least as large as the sheet thickness, then  $T/D$  also represents the punch length to diameter ratio. When this ratio exceeds 2.5, buckling under compressive load is a strong possibility. Therefore, in Fig. 3(a), the allowable  $T/D$  ratio plateaus at 2.5, even for sheet materials having low shear strength.

**Hole Location.** In addition to the shear deformation shown in Fig. 1, hole punching causes deformation of metal in the vicinity of the hole, as depicted in Fig. 4. This has two consequences: distortion of the edges of sheet blanks, and cambering of long parts if a row of holes is punched off center. To avoid distortion of the blank edges, the edge of the hole should be at least  $2T$  away from the edge. This same limitation applies to the distance between the edge of the hole and any other feature, such as another hole or flange. The residual stress leading to cambering, however, can be prevented only by punching holes on the centerline.

**Filters and grates** are often formed by punching an array of holes in the sheet (Fig. 5).

**Fig. 4** Edge distortion and cambering caused by hole punching near an edge or in an off-center row. Source: Ref 1

**Fig. 5** An array of holes punched in sheet metal to form a filter or grate. Reducing the number of holes and increasing their size reduces tool wear and punching loads.

Within the constraints of functionality of the filter or grate, the hole diameter and number of holes should be considered from the point of view of die maintenance (Ref 3). For example, for a given area of hole openings, the total circumference length of holes will increase with decreasing hole diameter. However, the shearing action during punching (Fig. 1) causes wear on the punch and die along this total circumferential length. The total shearing force also increases with increase in this circumferential length. For a given area of hole openings, therefore, increasing the hole diameter will reduce the total wear and total punching force. Increasing hole diameter will also avoid the punch force limits given by Fig. 3.

## Flanging

Part strengthening and attachment surfaces can be accomplished in sheet metal parts by forming a flange at the edge of the part. The bending process used to form flanges subjects the material to tension on the outer convex surface and compression on the inside concave surface (Fig. 6). A neutral axis, separating tensile and compressive deformation zones, is located at the centerline of thin sheet but shifts closer to the inside radius in bending of thick sheet. Plastic deformation occurs only within the curved section.

The maximum strain ( $e$ ) at the outer surface of the sheet during bending is given by:

$$e = \frac{T}{2R} \quad (\text{Eq 2})$$

where  $T$  is the sheet thickness and  $R$  is the bend radius. This strain level is usually achieved after the bend angle reaches about  $90^\circ$ . Further bending, even to  $180^\circ$ , does not increase the strain beyond this value, but it does increase the width of the plastic deformation zone (Ref 4).

**Defects.** One consequence of the stresses in bending is the possibility of fracture on the convex surface (Fig. 7). That is, the strain expressed in Eq 2 must be less than the fracture limit strain of the material. Generally, the fracture limit in bending is given as a minimum bend radius, expressed as a multiple of the sheet

thickness, i.e., the inverse of Eq 2. Materials having a large strain at fracture, therefore, have small  $R/T$  ratios, permitting small bend radii for a given sheet thickness. Tables of these limits are available in a number of references (Ref 4, 5). Typically, the limiting values for  $R/T$  are 0.3 to 0.7 for soft metals, 0.6 to 1.2 for harder metals, and 2 or greater for hard-to-form materials. For example,  $R/T$  values for titanium and zirconium exceed 3.

Another consequence of the stress and deformation in Fig. 6 is elastic recovery of the plastic deformation. This results in springback of the sheet so that the final bend angle of the sheet will be slightly larger than the angle of the bending die. Die designers have various means for compensating for elastic springback; however, the part designer should be aware that the degree of springback, and the difficulty of accommodating it, increases with increasing yield strength of the sheet, increasing bend radius, and increasing sheet thickness.

When straight-line bends are made in a part, localized stresses occur at the intersection of the bend and the plane of the part. In these regions, tensile stresses during bending may cause small tears and compressive stresses may lead to localized wrinkling. Notches added to the part pattern, as illustrated in Fig. 8, relieve these localized stresses and should be used if they don't interfere with the part function. Typical notch radii are  $2T$ . Such radii not only avoid

localized tearing or wrinkling during bending, they also serve to reduce stress concentrations due to applied loads during subsequent use of the part, decreasing the probability of fatigue failures at those points.

**Contoured Flanges.** Often it is useful to form a flange on a contoured profile (Fig. 9). As in the case of straight flanges described previously, the strains due to bending must be in the formability range of the material, in accordance with the strain described in Eq 2. In contoured flanges, in addition to this bending strain, a strain also occurs at the edge of the flange. For convex (compression) flanges, the outer radius of the blank decreases, causing compression and possible wrinkling in the flange. The strain at the flange edge is:

$$e = -W/R_2 \quad (\text{Eq 3})$$

where  $W$  is the flange width and  $R_2$  is the flange profile radius (not the bend radius). In this case, the strain is compressive and should not exceed 3% to avoid wrinkling. An example of a convex flanged part is shown as type B in Fig. 9.

For a concave (stretch) flange, the flange edge is in tension because the profile radius increases during the flange formation. Equation 3 applies for stretch flanges, as well, except that the strain is tensile. The ratio of flange width to profile radius in this case should not exceed the fracture strain of the sheet material with a sheared edge, which is always less than the fracture strain of the rolled sheet surface during bending. Typically, this limit is 10% for easy-to-form alloys.

In Fig. 9 the flange is formed perpendicular to the plane of the sheet, but along a curved line in the plane of the sheet. Other applications require strengthening flanges on a part that is

**Fig. 6** Illustration of the deformation during bending of sheet. The convex surface undergoes tension and the concave surface undergoes compression, with the neutral axis (zero deformation) at or near the centerline. Source: Ref 1

**Fig. 7** Cracking defects on the convex surface and wrinkling on the concave surface during bending. Source: Ref 1

**Fig. 8** Use of notches at the intersections between bend lines and sheet planes relieves stresses that can cause failure at those points. Typically the notch radii are  $2T$ . Reprinted with permission. Source: Ref 3

Type A

Type C  
Concave (stretch)  
curved bend flange  
(metal in elongation)

**Fig. 9** Flange formation on a curved profile in the flat plane of the part. Convex profiles lead to compression in the flange and possibly wrinkling; concave profiles involve stretching and possibly cracking. Reprinted with permission. Source: Ref 3

also formed into a contour out of the plane of the sheet, as shown in Fig. 10. In this case, the flanging operation takes place first, followed by contouring in steel dies, or in a roll-forming operation. In either case, the flange undergoes tension or compression, depending on the orientation of the flange relative to the contoured sheet. If the flange is on the convex side of the contour curvature, the resulting tensile stresses may cause cracking at the edges of the flanges. If the flanges are on the concave side, the compressive stresses may lead to buckling and wrinkling.

For flanges on a curved profile (Fig. 9) as well as on a contoured part (Fig. 10), round notches cut into the undeformed blank will alleviate the tensile and compressive stresses that may lead to defects. These notches are illustrated in Fig. 11 for convex and concave flanges. Alternatively,

**Fig. 10** Flange formation on a contoured part. Tearing can occur on the edges of flanges on the convex side of the contour (a), while wrinkling can occur in flanges on the concave side (b). Source: Ref 1

**Fig. 11** Notching to avoid (a) wrinkling or (b) cracking during flange forming on contoured parts. Source: Ref 1

in convex compression flanges, flutes may be formed into the flange, as shown in Fig. 12, to prevent buckling.

**Bend Orientation.** A further influence of material on bending involves the mechanical texture in the material. Sheet metal is produced by hot rolling an ingot of the metal in numerous rolling passes to a typical thickness of 2.0 to 2.5 mm (0.08 to 0.1 in.). During hot rolling, any inclusions and impurities in the material become plastic and elongate along with the base metal. The resulting hot-rolled sheet contains elongated stringers of impurities in the rolling direction. The hot-rolled sheet is then descaled and cold rolled to finished thickness (<1 mm, or 0.04 in.) for sheet forming. The impurity stringers remain during cold rolling, giving the sheet metal a mechanical texture or fiber in the rolling direction. As a result, ductility of the sheet is lower when the stress is perpendicular to the stringers than when the stress is parallel to the stringers. When the sheet metal undergoes bending deformation, the tensile stress shown in Fig. 6 will lead to cracking more readily if it is perpendicular to the stringer direction. Therefore, bend axes in parts should be oriented perpendicular to the stringer direction so that the tensile stress is parallel to the stringers. Taking this factor into account, Fig. 13

**Fig. 12** Formation of flutes on a convex flanged part to control wrinkling. Reprinted with permission. Source: Ref 3

**Fig. 13** Preferred orientation of bends in sheet metal to avoid cracking due to inclusion alignment in the sheet. Source: Ref 1

illustrates preferred orientations of the bend axis relative to the rolling direction of the sheet.

## Beads and Ribs

Indentations in the form of beads or ribs (long beads) can be formed in sheet metal to increase the localized strength and stiffness of the part. They are commonly used on flat sections of sheet metal parts for this purpose. In addition, ribs are used around holes to strengthen the area and provide a stiffer base for attachment of mating parts. For example, a circular bead that is 27 in height increases the stiffness of the part in the vicinity of the bead by six times and reduces the maximum stress by 66%. Examples of beads and ribs are shown in Fig. 14. Another example was shown previously in the flutes formed in the flange of Fig. 12.

Beads and ribs are formed by stretching metal to fill grooves in the die. A rubber pad or a metal punch is used for this operation. Because the metal is stretched, deep narrow ribs may exceed the formability limit of the sheet. In addition, in rubber pad forming, the pressure required to form the material increases with increasing sheet thickness and decreasing radius of the rib. For highly formable materials such as annealed low-carbon steel and aluminum, the maximum depth of ribs is approximately 5 times the sheet thickness, and the minimum bottom radius is approximately 10 times the sheet thickness. A table of data describing the forming limits for beads and ribs is given in Ref 6.

## Large Recesses

Large recesses or cavities are formed in sheet metal by stretching and drawing. Such operations are the most taxing of the sheet-forming operations because the strains are great and the combinations of strains that occur in complex shapes make simple rules of thumb on formability limits difficult to formulate. In their simplest forms, stretching and drawing are illustrated in Fig. 15.

**Stretching.** During stretching (Fig. 15a), the sheet metal blank is clamped and a metal punch or hydraulic pressure is applied to stretch the

sheet into a partial hemispherical shape. During stretching, the metal thins as it expands and may reach the ductility limit of the material. Stretching operations are used to form large hemispherical recesses or large parts having

**Fig. 14** Beads and ribs. (a) Cross section of a bead or rib formed in sheet metal for strengthening. (b) Concentric ribs formed around a hole to strengthen and stiffen the part.  $R$ , radius;  $T$ , stock thickness. Source: Ref 1

curvature in one or two planes. Stretching, on a much smaller scale, occurs during bead and rib forming, as described in Fig. 12 and 14.

The dominant material parameters affecting stretchability are the material's work-hardening index and strain-rate sensitivity. Greater work-hardening ability and rate sensitivity spreads the tendency for thinning to material surrounding the thinning region, thus delaying the formation of tears in the material. Materials with low work-hardening and rate-sensitivity indexes, however, allow rapid thinning of material at any point of discontinuity, leading to tearing at low strains.

**Deep Drawing.** Drawing (Fig. 15b), is a much more complex deformation process that involves a variety of tensile and compressive stress states. In this case, the sheet blank is pressed in a hold-down plate but not prevented from sliding. As the punch contacts the sheet, the sheet begins to stretch from around the punch radius. At the same time, material in the flange region starts to draw in from beneath the hold-down plate. Because the material in the flange area is decreasing in diameter, it undergoes compression in the circumferential direction. The hold-down plate provides vertical constraint that prevents wrinkling of the flange due to this circumferential compression. Meanwhile, as metal flows around the die radius, it undergoes bending and unbending. Once around the die radius, the metal continues to stretch in the axial direction and collapse onto the punch. This deformation mode is most severe because the metal must stretch in the axial direction without contracting in the circumferential direction. This plane-strain mode of deformation may lead to tears at the bottom of the cup where the thinning is greatest.

Increasing the ratio of blank diameter to cup diameter increases the plane-strain stretching stress at the bottom of the cup. As a result, each material has a limiting draw ratio (LDR), or ratio of maximum blank diameter to cup diameter. For example, under standard drawing tool conditions (die radius, punch radius, clamping pressure), the LDR for aluminum alloys is 2.1, for copper alloys 2.2, for steels 2.3, and for titanium alloys 2.6. The reason for this wide

discrepancy is the anisotropy of the sheet material, as measured by the  $R$ -value (ratio of width strain to axial strain in a tension test). Materials having high  $R$ -values will deform more in the plane of the sheet and less through the thickness, thus allowing more deformation before thinning and tearing.

In addition to materials parameters, tooling parameters also affect the LDR. As shown in Fig. 16, the LDR increases as the die radius increases. This effect is the result of less concentration of bending stresses as the material moves around the die radius from the flange into the wall of the cup. The punch radius also affects LDR, as shown by the family of curves in Fig. 16. The optimum value is a punch radius-to-sheet thickness ratio of 10.

As a result of this limitation on the amount of diameter reduction that can be accomplished in one drawing operation (LDR), deep cups require several drawing steps, each one requiring its own tool set. Alternatively, the cans used extensively for beverages are made by one drawing operation to form a shallow cup, followed by ironing processes that thin and extend the wall of the can.

Drawing of box shapes involves further complications in metal flow than described in Fig. 15(b). The corners of drawn boxes involve combined stretching and drawing deformation that can exceed the formability limits of the material. This effect limits the box depth and corner radius that can be accomplished in boxes, as illustrated in Fig. 17. In this result (for stainless steel), the allowable depth of the box decreases and the allowable corner radius increases as the strength of the material increases (and ductility decreases). Formability is also influenced by stock thickness, as discussed in the following example.

**Example: Effect of Metal Thickness on Deep Drawing of Shells (Ref 7).** The stock thickness and its relation to the diameter or width of the blank affects the formability of round, square, and rectangular shells. Stock thickness also affects the depth of shell that can be drawn in one operation.

**Round Shells.** The number of drawing operations needed to produce a finished round shell

**Fig. 16** Limiting draw ratio (LDR) as a function of die radius in deep drawing of brass cups. Also shown is the effect of punch radius on LDR; The optimum value of punch radius is 10T. Reprinted with permission. Source: Ref 3

depends on blank diameter, depth and diameter of the shell, properties and thickness of the work metal, and draw-die and punch-nose radii.

The ratio of the punch diameter to the blank diameter ( $d/D$ ) is a simple and practical measure for use in determining formability. The maximum  $d/D$  ratio depends markedly on the metal thickness and the draw-die radius. The ratio of metal thickness to blank diameter ( $t/D$ ) reflects the principle of volume constancy between the blank and the shell and, as shown in Tables 1 and 4, affects the formability factor  $d/D$ . The formability factors in Table 1 are multiplied by the blank diameter, or by the previous shell diameter, to obtain the shell diameter. For each redraw, the factors increase, indicating a decrease in formability. The size of draw-die radius also has an effect on the formability factors, as footnoted in Table 1. When the factors given in Table 1 are not exceeded, three or four draws can be made in 1010 steel without annealing if the punch-nose radius is at least 75% of the draw-die radius.

The ratio of draw depth to shell diameter, and the size of the draw-die radius, depend on the  $t/D$  ratio, as shown in Table 2.

When drawing flanged round shells, the ratio of the flange diameter to the shell diameter

**Table 1** Formability factors ( $d/D$  ratios) for drawing round shells without flanges from 1010 steel(a)

Stock thickness, % of blank diam	Formability factor ( $d/D$ ratio)				
	First draw	Second draw	Third draw	Fourth draw	Fifth draw
2.0	0.48	0.73	0.76	0.78	0.80
1.5	0.50	0.75	0.78	0.80	0.82
1.0	0.53	0.76	0.79	0.81	0.84
0.6	0.55	0.78	0.80	0.82	0.85
0.3	0.58	0.79	0.81	0.83	0.86
0.15	0.60	0.80	0.82	0.85	0.87
0.08	0.63	0.82	0.84	0.86	0.88

(a) For draw-die radii of 8*t* to 15*t* (*t* is stock thickness); factors may increase about 2% for draw-die radii of 4*t* to 8*t*.

( $D_p/d$ ) and the  $t/D$  ratio both affect the maximum depth-to-diameter ratio of the shell (Table 3). The formability factors  $d/D$  shown in Table 4 should not be exceeded during the first drawing operation for a flanged round shell.

**Square or Rectangular Shells.** As noted, drawing of square or rectangular shells subjects the metal in the corners to compressive stresses. Metal in the sidewalls is subject to tensile stresses after the metal has been drawn over the die radius. Compressive stresses in the sidewalls are caused by the flow of metal from the corner areas.

Compression of the metal from the corner areas into the sidewalls depends on the ratio of the inside vertical corner radius of the shell to the width of the shell ( $r/w$ ). Resistance of the metal to bending and wrinkling depends on the

ratio of metal thickness to blank width ( $t/W$ ). Formability factors ( $0.71\sqrt{r/h}$ ) for square or rectangular shells drawn in one operation from 1010 steel are listed in Table 5; formability factors for less ductile metals are up to 10% larger.

Maximum ratios of depth to width for square or rectangular shells drawn in one operation are given in Table 6, these values are based on the ratio of shell corner radius to shell width ( $r/w$ ), and on the ratio of metal thickness to blank width ( $t/W$ ).

The number of drawing operations needed is influenced by the ratio of shell depth to shell width ( $h/w$ ), and the ratio of the inside vertical corner radius of the shell to the width of the shell ( $r/w$ ), as shown in Fig. 18. Areas A, B, and C below curve 2 in Fig. 18 represent the limits

**Table 2** Maximum depth-to-diameter ( $h/d$ ) ratios for drawing round shells without flanges from 1010 steel(a)

Drawing operation	Maximum $h/d$ ratio for steel with thickness of the following percentages of blank diameter:					
	2.0–1.5%	1.5–1.0%	1.0–0.6%	0.6–0.3%	0.3–0.15%	0.15–0.08%
First	0.94–0.77	0.84–0.65	0.70–0.57	0.62–0.50	0.52–0.45	0.46–0.38

0.05	0.15	0.15	0.15	0.15

(a) Ratio of inside vertical corner radius of shell to width of shell

for drawing square or rectangular shells in one operation. Shells in areas D, E, and F above curve 1 need two or more operations. The space between the curves 1 and 2 represents shells that are borderline for drawing in one operation. Shells in areas A, B, and C have a stock thickness of no more than 0.6% of the blank width; in areas D, E, and F, the stock thickness is not less than 2% of blank width.

Each area in Fig. 18 represents shells with certain characteristics. Area A represents shallow shells with small inside corner radii and an  $r/(w-h)$  ratio of no more than 0.17. With these shells, only a small amount of metal moves into the sidewalls from the corner areas; thus, the sidewall height is constant. Typical blank development for area-A shells is shown in Fig. 19.

Area B in Fig. 18 represents shallow shells with medium-size corner radii and an  $r/(w-h)$  ratio of 0.17 to 0.4. The movement of metal into the sidewalls from the corner areas causes earing in this type of shell. Figures 19(c) and 20 show a typical corner of a blank for an area-B shell.

Area C in Fig. 18 represents shells with medium to large corner radii and with an  $r/(w-h)$  ratio of more than 0.4. The compression of metal into the sidewalls of these shells causes

considerable earing. One method of developing the corner of the blank for wide or shallow area-C shells is illustrated in Fig. 20.

Workpieces in area D in Fig. 18 have an  $h/w$  ratio no greater than 0.65, and a blank shaped as shown in Fig. 19(d). Area F represents shells

Fig. 19 Corner-layout method, and typical corners, for blanks for square or rectangular shells in areas A, B, and D in Fig. 18. Corner shape varies with shell dimensions, and the shape typical of area B and that typical of area D extend into adjacent areas.

0.10	0.60	0.55	0.50	0.45
0.05	0.40	0.35	0.30	0.25

(a) Ratio of inside vertical corner radius of shell to width of shell

Fig. 18 Dimensional relations defining six areas of formability of square or rectangular drawn shells of 1010 steel. See text for details.

Fig. 20 Corner-layout method for wide shells with large corner radii in areas B and C in Fig. 18

with an  $h/w$  ratio greater than 0.7. The ranges of areas D and F overlap into area E.

The procedure for laying out the corners of blanks for shells in areas A, B, and D in Fig. 18 with reference to Fig. 19(a), is:

1. Lay out a square or rectangle by drawing lines through the loci of the workpiece corner radii. These lines are the primary datum lines.
2. The width of metal needed for the sidewall and bottom radius is  $h + 0.57r_b$ , where  $h$  is the shell depth, in inches, and  $r_b$  is the bottom inside radius, in inches. This width is added to each side of the layout of step 1, from the primary datum lines.
3. The corner radius  $R$  of the blank, which provides the metal needed from each corner of the shell, is:

$$R = \sqrt{r^2 + 2hr - 0.86r_b(r + 0.16r_b)}$$

where  $r$  is the inside corner radius of the workpiece, in inches. For parts in area D, radius  $R$  is increased by 10 to 20%.

4. Lay out corner radius  $R$ , using the loci of the workpiece corner radii as center points, so as to intersect the lines drawn in step 1 at points  $b$  and  $c$ .
5. Bisect  $ab$  and  $cd$ . Through the dividing points  $e$  and  $f$ , draw  $gh$  and  $ij$  tangent to arc of corner radius  $R$  drawn in step 4. (These tangents may coincide (Fig. 19b), they may cross each other outwardly (Fig. 19c), or they may cross each other inwardly (Fig. 19d).)
6. Blend the intersections of the tangents and the edges of the blank with an arc of radius  $R$ . When the tangents intersect inwardly, blend the intersections with an outward arc of radius  $R$  (detail A in Fig. 19a).

Shells in area B in Fig. 18 and shallow or wide shells in area C have a larger amount of metal compressed into the sidewalls than in area A. The blank is adjusted for this by increasing the metal for the corners and decreasing the metal for the sidewalls, as described subsequently, with reference to Fig. 20:

1. Start the blank layout using steps 1, 2, 3, and 4 in the preceding procedure. If the corner radius is not the same as the bottom

radius, the loci of the bottom radii establish secondary datum lines from which the metal for the sidewalls found in step 2 in the six-step procedure previously listed is projected.

2. The corrected corner radius  $R_c$  is calculated by the formula:

$$R_c = R[0.074(R/2r)^2 + 0.982]$$

3. The width of metal for the sidewalls is reduced by  $h_w$  and  $h_l$ , calculated by the formulas:

$$h_w = yR^2/(w - 2r) \text{ and } h_l = yR^2/(l - 2r)$$

Values for factor  $y$  are given in Table 7.

4. Blend the intersections of the width, length, and corner radii of the blank by making  $R_w$  tangent to  $R_c$  and the blank width; and  $R_l$  tangent to  $R_c$  and the blank length.

Square shells in area F, and in area C with a large  $h/w$  ratio, can be drawn from round blanks. The blank diameter is determined according to the following formula:

$$D = 1.13 \times \sqrt{w^2 + 4w(h - 0.43r) - 1.72r(h + 0.33r)}$$

Rectangular shells in areas C and F with large  $h/w$  ratios usually are drawn from blanks with semicircular ends connected by two parallel sides; their length is the difference between the length and width of the shell.

## Scrap Reduction

Reducing the amount of scrap in sheet-forming operations can be accomplished in two ways:

- By clever nesting of the blanked shapes so that the unused material is minimized
- By prevention of defects and other causes for rejection of finished parts

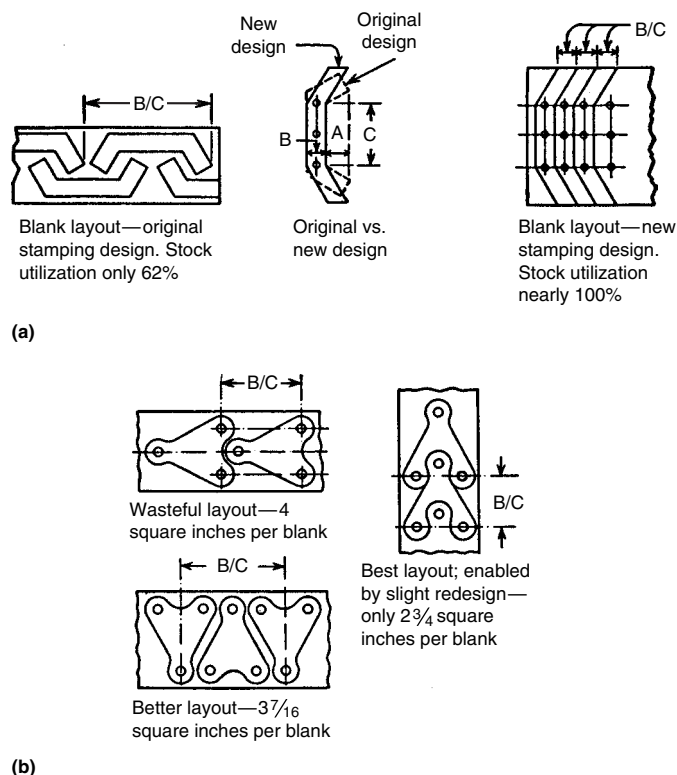

The first approach involves careful consideration in process preplanning and may be enhanced by part redesign. The second approach involves use of advanced techniques for analysis of deformation during sheet forming to prevent defects. Although the scrap can be recycled, handling and reprocessing of the scrap are additional steps with costs that detract from profitability. Therefore, using both approaches in early part design stages enables scrap minimization to be an important element in the product realization system.

**Blank Layout.** Part redesign can be used to reduce the amount of scrap, as shown by the examples in Fig. 21. In Fig. 21(a), the original design involved tab ends that were best arranged in a nesting pattern of alternating orientation of the blanks. By altering the design to decrease the angle of the tabs and orienting the edge of the tabs to be perpendicular to the main portion of the blank, the blanks can now be nested for complete utilization of

**Table 7 Factor  $y$  for corner radius of blank for a square or rectangular shell in area C in Fig. 19**

material with no scrap. In Fig. 21(b), alternating orientation of the blanks reduced scrap somewhat, but a slight redesign of the part (and resulting blank shape) allowed the tab of one blank to be nested in a recess of the next blank.

**Process Analysis.** Applying the best analytical tools during the part design stage of product development will increase the likelihood of success and reduce the probability of defects during production, with its scrap loss. One major tool is the diemaker's experience, generally the result of many years of observations and mini-experiments. Some of this experience is captured in sheet-forming and die-making handbooks. This approach is limited, however, to the geometric features and materials that make up the diemaker's experiential database.

When new materials or unusual shapes are encountered, a well-refined technique has been established that uses circular grids, stamped on the sheet metal blanks, which are measured after the forming process is complete (Ref 8). Grid measurements indicate the amount of strain that has occurred and are compared with a formability diagram of the material. Strains that are close to the materials' forming limits

may be reduced by alteration of the tooling or lubrication. Of course, this approach requires manufacture of the tooling before the process can be examined, which is a costly and time-consuming task.

Another approach involves the use of computerized simulation of the sheet forming process in conjunction with a forming limit diagram for the material (see the articles in the section "Process Design for Sheet Forming" in this Volume). Sophisticated analysis programs that solve the equations for plastic deformation of material are used to simulate the metal flow during sheet forming and calculate the strains in the material. Comparing these results with the material forming limit diagram indicates the areas of potential failure. Such programs can be used to determine alterations in the tooling and/or lubrication method that reduce the probability of failure.

Both the grid analysis and the computer simulation approaches to sheet-forming process analysis are described in more detail elsewhere in this *Handbook*. From a product design perspective, however, both methods should be considered in the early part design stages to evaluate design alternatives that will reduce the risk of failure during processing,

and the subsequent scrap loss in defective parts.

# Cutting Operations

CUTTING OPERATIONS in metal fabrication industries include various mechanical, chemical, and thermal methods. Mechanical methods involve fabrication equipment such as shears, iron workers, and nibblers. Punch presses and press brakes also are sometimes used for shearing a few pieces or are used temporarily when more efficient equipment is not available. Production shearing, however, is usually done in machines that are designed for this operation (see the article “Shearing of Sheet, Strip, and Plate” in this Volume). Mechanical cutting is also done with machining equipment such as band saws or abrasive waterjet cutting. Nonmechanical methods of cutting include material removal by chemical and/or thermal processes. These methods include gas cutting, electric arc cutting, and laser cutting. This article provides a general overview on these mechanical and non-mechanical cutting methods, with additional information in separate articles in this Volume.

## Mechanical Methods of Cutting

The most prevalent equipment used for mechanical cutting includes shears, iron workers, nibblers, and band saws. Each has specific applications for which it is efficient and cost-effective.

**Shears** are normally used to prepare large, relatively thin materials ( $\leq 25$  mm, or 1 in., thick) by cutting them to final dimensions. The two principal shearing variations are straight-knife shearing and rotary shearing. In straight-knife shearing, the work metal is placed between a stationary lower knife and a movable upper knife. As the upper knife is forced down, the work metal is penetrated to a specific portion of its thickness. Straight-knife shearing is used for squaring and cutting flat stock to the required shape and size. It is usually used for producing square and rectangular shapes, although triangles and other straight-sided shapes are also sheared with straight knives. Rotary shearing is used for producing circular or other contoured shapes (see the article “Shearing of Sheet, Strip, and Plate” in this Volume).

Straight-knife shearing is the most economical method of cutting straight-sided blanks from stock no more than 50 mm (2 in.) thick. The process is also widely used for cutting sheet into blanks that will subsequently be formed or

drawn. Because shear gaging can be set within  $\pm 0.13$  mm ( $\pm 0.005$  in.), the shearing process is generally limited to  $\pm 0.4$  mm ( $\pm 1/64$  in.) tolerances in 16-gage material. The tolerance range increases with thickness.

Straight-knife shearing is seldom used for shearing metal harder than approximately 30 HRC. When extremely soft, ductile metal (especially thin sheet) is sheared, the edges of the metal roll, and large burrs result. As the hardness of the work metal increases, knife life decreases for shearing a given thickness of metal.

In general, it is practical to shear flat stock up to 38 mm (1½ in.) thick in a squaring shear. Squaring shears up to 9 m (30 ft) long are available (even longer shears have been built), and some types are equipped with a gap that permits shearing of work metal longer than the shear knife.

**Iron workers (heavy-duty shears)** are used primarily for preparing structural shapes such as bars, angles, and T-bars (see the article “Shearing of Bars and Bar Sections” in this Volume). Like the shears used for plate and flat sheet, iron workers leave a square butt edge that may require further preparation for heavier sections before welding. The production shearing of bars and bar sections is usually done in machines with a throat opening designed for large, bulky workpieces. Guillotine and multipurpose (combination) machines are widely used for welding preparation. The multipurpose machines feature interchangeable punches and dies for shearing, punching, and coping. Squaring shears, normally used for sheet and plate, can also be used for cutting bar stock to length. Punch presses and press brakes can be provided with appropriate tooling for cutting operations.

**Nibblers** are power tools that “nibble” small pieces away from the material being worked.

Fig. 1 Schematic of nibbler cutting action

They range in size from hand-held machines to large floor-mounted equipment. Because the hand-held machines are portable, they are suitable for preparation of large parts on site, where thermal cutting may be impractical.

Nibblers can cut flat sheet of both ferrous and nonferrous metals, as well as of fiberglass and plastic. Corrugated and trapezoidal metal sheets can also be cut. Nibblers are frequently used to make edge preparations for welding of stainless steels and nonferrous metals. Unlike shears, which can curl or distort the separated pieces, nibblers remove material, creating a kerf or cutting slot; therefore, distortion of the sheet is eliminated.

Nibblers use a reciprocating punch and stationary die to accomplish the cutting process. During operation, the punch approaches and makes contact with the material being worked. The stroke of the punch compresses the material; the increased compression causes the material to deflect. As the shear point of the material is exceeded, the material is penetrated by the punch. The material then breaks (Fig. 1), and the break continues to widen until a cone-shaped chip is ejected. The punch is then withdrawn. The resulting edges are usually free of burrs. If burrs do occur, the gap between the punch and die is too wide (Fig. 2). On some equipment, this gap can be varied.

Fig. 2 Schematic of nibbler setup with excessive gap between the punch and die, resulting in the formation of burrs on the workpiece

Because of their unique cutting action, nibblers do not need to be forced into the material. This so-called "natural feed" requires only light operator pressure. Also, the weight of the nibbler does not need to be supported solely by the operator: Once the nibbler has started cutting, the weight of the tool is supported by the sheet being worked. Nibblers are considered to be very safe to operate.

Some equipment is available with guide fences (similar to those used with circular saws), circle-cutting attachments, and template guides. Punches and dies on some nibblers can be resharpened; however, in many cases these parts are disposable. For optimal punch and die life, cutting oil should be used to lubricate the cutting process.

**Band Saws.** Sawing of a metal can be done with power band saws, hacksaws, and circular saws (see the article "Sawing" in *Machining*, Volume 16 of *ASM Handbook*, 1989). Each of these methods is used in cutoff operations (cutting pieces to a required length), although band sawing also provides a method of cutting contours. The most satisfactory range of material hardness for sawing is approximately 180 to 250 HB, but steels up to 400 HB and some free-machining steels up to 450 HB can be sawed at reduced cutting rates.

In general, hacksawing and band sawing involve lower-cost machines with greater versatility and a larger cutting range. Circular sawing produces the smoothest finishes and the closest dimensional tolerances, especially on nonferrous materials. Table 1 compares the general characteristics of power band sawing, hacksawing, and circular sawing. The tool life and tool cost ratings in Table 1 are only general and may change completely for different applications.

Band saws have a thinner cutting tool than the other sawing machines. Band sawing produces a kerf of approximately 1.6 mm ( $1/16$  in.); hacksawing and circular sawing produce kerfs of 8 and 9.5 mm ( $5/16$  and  $3/8$  in.), respectively. Because the saw band is thinner than the other sawing tools, less power is required for cutting, and binding in the kerf is less likely. Another advantage of band

sawing is that the uniform, continuous cutting action produces even wear over the entire length of the saw band. The blades for band saws are also changed less frequently, because they are longer than the blades in other types of saws.

Band saws can be used to cut contours or straight lines, depending on the type of machine. Most band saws are designed for either vertical or horizontal movement of the saw band, although some manufacturers offer combination vertical-horizontal band saws for light- to medium-duty cutting. The band saws available include contour band saws, cutoff band saws, tilt-frame universal band saws, and plate band saws.

Contour band saws are vertical types that allow an operator to cut various contoured shapes by guiding the blade along a layout line. These machines can use very narrow bands for cutting small radii as well as wider bands for larger radii and straight cuts. Cutoff band saws can be either horizontal or vertical. They cannot cut contours but can make straight cuts very efficiently. Some machines can cut angles and compound miters in solids as well as structural shapes.

The two most widely used types of band saw blades available are carbon and bimetal. Both types have hardened tooth tips for good wear resistance. Carbon steel blades are made from very high carbon tool steel and have either flexible backs or hard backs. The hard-back type has a heat treated back for better strength and straighter cuts. Bimetal blades are made with high-speed steel that is electron-beam welded to a lower-alloy backing steel. The result is a blade with the cutting properties of high-speed steel at the tooth tips and the flexibility and strength of a heat treated alloy on the backing or carrier band.

Bimetal blades should be used when cutting difficult-to-machine materials and for high-production sawing. Bimetal blades will last longer than carbon blades, and they typically cut at ten times faster rates than those achieved with carbon blades. Carbon steel blades are most widely used for cutting of nonmetallic materials. However, they also do a satisfactory job when cutting low-carbon and low-alloy steels and perform well when cutting nonferrous alloys (for example, aluminum).

Table 2 lists the recommended speeds and cutting rates for many commonly sawed materials. The numbers are based on sawing of solid materials in the fully annealed condition. The data given should only be considered as a starting point; actual speeds and cutting rates will vary due to material variations and the type and condition of the saw that is used. Table 2 only applies when using bimetal blades. Carbon steel blades cannot be run at the band speeds shown because the heat generated at these speeds will cause them to soften and fail immediately.

When cutting pipes, tubes, or structural shapes, it is necessary to compute slower cutting

rates than those given in Table 2. The cutting rates should be modified as follows:

Part size		Percentage of speed shown in Table 2
mm	in.	
<4.8	< $3/16$	40
4.8–9.5	$3/16$ – $3/8$	50
9.5–16	$3/8$ – $5/8$	60
>16	> $5/8$	70

Proper break-in is important to ensure optimal blade performance. When using a new blade, cutting at the full rate will cause fracturing of the very sharp tooth edges. Breaking in a new blade removes the ultrasharp edges and allows the blade to retain its cutting ability longer. A new blade can be broken in by running at the recommended band speed, but reducing the feed pressure for the initial cuts. When cutting work-hardening materials (for example, nickel alloys), it is important to use enough feed pressure to generate a chip and to prevent work hardening of the cut surface.

Knowledge of chip formation is helpful in finding the optimal speeds and cutting rates to use when band sawing. When a blade cuts, each tooth tip penetrates the workpiece and shears off a chip of material. Parameters such as band speed, feed, lubrication, and blade tip design all affect chip formation.

Visual examination of the chips can be used to determine proper speeds and cutting rates (Table 3). In general, the optimal conditions are present when the chips are curled and silver in color, indicating they were properly formed without excessive heat generation.

## Gas Cutting

Gas cutting is essentially a process of controlled oxidation of metal. Because of the properties of iron and its oxidation at elevated temperature, gas cutting is most efficient in cutting carbon, low-alloy, and some high-alloy steels. Many high-alloy steels and most nonferrous metals either resist continuous oxidation or in other ways upset the delicate balance of physical and chemical reactions required for uniform cutting. As a result, cutting of such materials becomes more a matter of progressive melting than of controlled oxidation, and the cut edges generally are round and irregular. To overcome this, chemical flux or metal powder (principally iron powder) can be added to the oxygen jet to provide the reactions necessary for controlled cutting. Chemical fluxes and metal powders are used for cutting stainless steel, cast iron, and nonferrous metals in mills, foundries, and fabricating shops. Equipment for such cutting is somewhat awkward, and speeds are lower than those of some arc cutting processes.

Various gas cutting processes have been known as flame cutting, burning, oxyfuel gas cutting, and oxygen cutting. The terms *oxyfuel*

**Table 1 Cost and performance comparisons of hacksawing, band sawing, and circular sawing**

Characteristics	Type of machine(a)				
	Lowest				Highest

Tool life	H	→	B	→	C
Accuracy and finish	H	→	B	→	C
Kerf loss	B	→	H	→	C

(a) H, hacksawing machine; B, band sawing machine; C, circular sawing machine

gas cutting and oxygen cutting may be more accurate than other terms. However, all the terms mentioned previously have been used. Moreover, there can be some shift in the boundaries of cutting processes. For example, at least two arc cutting methods use oxygen to assist cutting. In another form of oxygen cutting, a laser beam is passed through the window of an oxygen-pressurized chamber and out a small orifice at the other end.

The various processes for gas cutting of ferrous metals are identified by the fuel gas that is used to produce the preheat flame. The commercially important processes are oxyacetylene cutting, oxynatural gas cutting, oxypropane cutting, and oxy-MAPP gas cutting. (MAPP is a trade name for a proprietary mixture of stabilized methylacetylene and propadiene.) Other fuel gases used include hydrogen, ethylene, methane, ethane, and butane.

For gas cutting of stainless steel and non-ferrous metals, and for faster cutting of cast iron

and oxidation-resistant ferrous alloys, two other methods are available: chemical flux cutting and metal powder cutting. Other gas cutting methods may be identified by the special purposes for which they are intended, such as oxyfuel gas gouging, oxygen lance cutting, and underwater gas cutting. These various types of oxygen cutting processes using oxyfuel gas and its modifications (i.e., flux cutting and metal powder cutting to cut oxidation-resistant materials) are discussed in more detail in the article "Oxyfuel Gas Cutting" in this Volume.

## Electric Arc Cutting

Arc cutting melts metal by heat generated from an electric arc. Because extremely high temperatures are developed, arc cutting can be used to cut almost any metal. Modifications of the process include the use of compressed gases

to cause rapid oxidation (or to prevent oxidation) of the workpiece, thus incorporating aspects of the gas cutting process. Arc cutting methods include air carbon arc, gas metal arc, gas tungsten arc, shielded metal arc, plasma arc, and oxygen arc cutting. The two methods of industrial importance are plasma arc cutting and air carbon arc cutting. Other methods include electric arc cutting using consumable tubular electrodes (the Exo-Process) and oxygen arc cutting (see the article "Electric Arc Cutting" in this Volume).

The past decade has seen a great increase in the use of plasma arc cutting, because of its high cutting speed. Technical features of oxyfuel cutting and plasma arc cutting are compared in Table 4. The process increases the productivity of cutting machines over oxyfuel gas cutting without increasing space or machinery requirements. The basic plasma arc cutting torch is similar in design to that of a plasma arc welding torch (Ref 1). (See also the article "Plasma Arc

**Table 2 Speed and cutting rates for cutoff band sawing with bimetal blades of selected ferrous and nonferrous metals**

(a) Based on the use of a 25 mm (1 in.) wide high-speed steel band, regular tooth form (except hook tooth form for metal thicker than approximately 250 mm, or 10 in.), raker set, to cut scale-free, solid bar stock up to 460 mm (18 in.) thick; based on the use of a cutting fluid, except for D2, D3, and D7 tool steels, which are cut dry

Welding” in *Welding, Brazing, and Soldering*, Volume 6 of *ASM Handbook*, 1993). For the cutting of metals, increased gas flows create a high-velocity plasma gas jet that is used to melt the metal and blow it away to form a kerf.

## Laser Cutting

Laser cutting melts a material by focusing a coherent beam of monochromatic light on the workpiece. The effectiveness of laser cutting in a particular application depends on the pulsing and focusing of the beam and on the reflectivity, absorption coefficient, thermal conductivity, specific heat, and heat of vaporization of the workpiece. The greatest use of lasers in metal cutting is primarily two-axis profiling of sheet goods that may otherwise have been blanked out by punch press or fabricated by hand after laborious layout of the pattern. Currently, most metal cutting falls within 9.5 mm (0.375 in.) and thinner, although CO<sub>2</sub> lasers are now competitive with plasma arc cutting for metal thicknesses of 13 mm (0.500 in.) and greater. The principal factor in the use of laser metal cutting is manufacturing methodology. Laser cutting is ideal for batch processes, just-in-time, or low- to medium-volume production. Most laser cutting work is performed on generic or multipurpose materials handling systems, as opposed to dedicated automation-controlled systems.

Table 5 compares the technical features of laser cutting with other cutting methods. Additional information is provided in the article “Laser Cutting” in this Volume.

## Abrasive Waterjet Cutting

Waterjet cutting uses a high-velocity stream of water to cut materials. Cutting of hard materials such as metals is done when the waterjet contains abrasives, in which case the method is referred to as abrasive waterjet cutting. Waterjet cutting has several advantages over other two-dimensional cutting methods and is an alternative to laser cutting, gas cutting, and plasma cutting (see Table 5 for a comparison of technical features). Advantages include:

- High cutting accuracy without leaving any frayed edges or burrs
- No distortion, because heat is not used in the cutting process
- Complex patterns can be cut without tooling
- Capable of cutting many different types of material, such as steel, aluminum, titanium, plastic, stone, rubber, glass, ceramic, and fiberglass

Figure 3 summarizes the capabilities of the laser beam, oxyfuel, plasma arc, and the abrasive waterjet in cutting a variety of metals. Current technology limits the abrasive

**Table 3 Visual examination of chips to determine adjustments in band saw parameters that are required to optimize machinability**

Form	Color	Appearance or condition	Recommended parameter adjustment

# Principles of Shearing, Blanking, and Piercing

Many shearing, blanking, and piercing operations are based on the same underlying principles of shear mechanisms, and an understanding of shearing theory enables one to understand the following operations (Fig. 1):

**shearing.** Cutting material with dies or blades.

*Shear* is an inclination between two cutting edges used for the purpose of reducing the required shear force. A shear is a tool for cutting metal and other materials by a closing motion of two sharp, closely adjoining edges.

**punching.** A general term describing the process of die cutting a hole in material such as sheet metal, plate, or some structural shape. A *punch* is the male part of a die set and usually the upper member.

**perforating.** A more specific term used in the stamping industry for die cutting of holes in material.

**piercing.** Penetration of material using a sharp-pointed punch, leaving a jagged hole similar to a bullet hole.

**extruding.** Forming of a flange around a hole in sheet metal.

**blanking.** Cutting or shearing of material to a predetermined contour from sheet or strip stock.

**notching.** Cutting of various shapes from the corner or edge of a strip, sheet, or part.

**nibbling.** Progressive notching at a high rate of speed, making either a smooth finished edge or a scalloped edge.

**lancing.** Cutting into a workpiece without producing a detached slug. Usually combined with forming, such as in production of louvers.

## Shear Action in Metalcutting

The shear cutting or punching action results from a closing motion of two sharp, closely adjoining edges on material placed between them. The material is stressed in shear to the point of fracture while going through three phases (Fig. 2):

1. *Deformation:* As the cutting edges begin to close on the material, deformation occurs

on both sides of the material next to the cut edge.

2. *Penetration:* The cutting edges cut or penetrate the material, causing fracture lines.

3. *Fracture:* The point where the upper and lower fracture lines meet. At this point the work is done, but in punching, the punch must continue to move through the material to clear the slug.

The shear cutting action produces four inherent characteristics found on both the parent material and the cut-off (or punched-out) part (Fig. 3). These characteristics are:

- Plastic deformation
- Vertical burnish-cut band
- Angular fracture
- Burr caused by the fracture starting above the cutting edge

The amount of each of these four characteristics depends on:

- Material thickness
- Material type and hardness

Fig. 1 Pressworking operations employing shearing principles. (See definitions in text.)

Fig. 2 Three phases of shear cutting

Fig. 3 Four characteristics of shear cutting

- Amount of clearance between cutting edges
- Condition of cutting edges
- Firmness of support of material on both sides of the cut
- Diameter of hole or blank in relation to material thickness

If all the preceding conditions are satisfied but the edge condition is still not acceptable, there are other methods that may be employed. One of the most common finishing methods is shaving, in which a small amount of material is removed to eliminate the fracture angle. Another is the fine blanking process, in which a special press or die set is used to compress the material in the shear plain during the cutting cycle and thus eliminate the fracture angle.

## Deformation

The type, hardness, and thickness of the material all have effects on the amount of deformation. Softer and thicker materials deform the most. Clearance between the cutting edges and the support of the material on both sides of the cut also have strong effects. Figure 3 shows a

Fig. 4 Single-cut flat bar shearing with holddown and no rear support, and with rear support

hole punched with excessive clearance: note the deformation around the top surface. Supporting the material is generally no problem in hole punching, because the punch holds the slug or blank firmly against the punch face. However, in making a straight shear cut on a long bar, it is necessary to use a holddown to keep the bar from twisting around the lower blade. The combination of tensile and compressive stresses that occur in metal cutting causes this twisting. A support opposite the holddown produces the best results. Note that, without the support, the material bends before fracturing, and an angular impression from the blade is left on the end of the bar (Fig. 4).

## Penetration

Penetration is the sum distance of the deformation and vertical burnish height. It is expressed as a percentage of the material thickness and is defined as the distance the punch must travel before the metal fractures. The percentage of penetration varies with the type and hardness of the material. As the material becomes harder, the percentage of penetration decreases (Fig. 5).

Penetration increases where holes are less than 1.5 times the material thickness due to the high compressive stress in the material cut zone.

## Clearance

The angular fracture and the quality of the cut, the punched hole, or the blank are greatly dependent on the amount of clearance between the two opposed cutting edges. Figure 3 shows the clearance as being the distance between the mating cutting edges. Without proper clearance,

Material	Penetration, %T
Aluminum	60
Copper	55

Nickel	55

Fig. 5 Penetration as a percentage of stock thickness, showing variation with material hardness

the material will not fracture cleanly. Figure 3 shows how upper and lower fractures should meet; if they do, a clean hole is produced with a minimum power requirement. With insufficient clearance, a defect known as secondary shear is produced, as shown in Fig. 6. The two fracture lines were not permitted to meet, leaving a ring of material that must be stressed to its point of fracture with a further expenditure of energy. The amount of secondary shear decreases as the clearance increases toward the proper clearance. Dull tools result in insufficient clearances as well as burrs.

Excessive clearance between the mating edges causes extreme plastic deformation, a large burr, and a high angle of fracture, as shown in Fig. 6. Therefore, proper clearance may be defined as that clearance which causes no secondary shear and a minimum plastic deformation and burring.

Proper clearance varies with the thickness and type of material. As shown earlier in Fig. 5, the amount of penetration or fracture depends on the type and hardness of the material. Clearance is expressed as a percentage of the material thickness and must be qualified as to whether it means clearance per side or total diametral (overall) clearance. Proper clearances are best found by trial and error. No formulas or tables are available that will give exact clearances, but the values given in Table 1 have worked well in short-run punching where it is important to select standard dies for punching materials in a range of thicknesses.

**Where to Apply Clearances.** Where the clearance is applied must be considered in blanking or punching to close tolerances. Figure 3 is a good illustration. The die is larger than the punch by the amount of clearance required to produce a clean fracture. If the hole is to be held accurately to size, the punch must be

Fig. 6 Effects of excessive and insufficient clearances

Table 1 Recommended clearances for punching

Material	Total diametral clearance, % of material thickness		
	Minimum	Best	Maximum
Copper, 1/2 hard	8	12	16
Brass, 1/2 hard	6	11	16
Mild steel	10	15	20
Steel, 0.50% C	12	18	24
Aluminum, soft	5	10	15
Stainless steel	12	18	24

that size and the die must be oversized to allow proper clearance. Conversely, if the operation is blanking of a disk that has to be accurately held, the die must be that size and the punch must be undersize to allow proper clearance.

A punched hole will shrink very slightly, which must be allowed for if high precision is required. The amount varies with the type and hardness of the material but normally does not exceed 0.05 mm (0.002 in.). Punching or blanking consistently produces very accurate parts. (Additional discussion of die and punch clearance is provided in the section "Die Clearances and Stripping Forces" in this article.

**Tool Life.** Clearance has a great effect on tool life. Maximum life is attained only when clearance is proper. Insufficient clearance greatly reduces tool life due to springback and cold welding of the material to the punch and die. In punching harder materials, insufficient clearance creates a much higher stress on the cutting edge and causes it to chip and break down.

Excessive clearance also has an adverse effect on tool life, caused by the material being stretched over the cutting edges, and causes the sharp edges to break down prematurely.

A good grade of die-cutting lubricant greatly extends punch and die life.

Punches wear at twice the rate of dies because a punch has to pass through the material twice, in

and out, whereas only the slug passes through the die.

## Stripping Force

The punching process requires two actions, punching and stripping. Forcing the punch through the material is simple in comparison with stripping or extracting the punch. A stripping force due to the resiliency or springback of the punched material grips the punch. Additional friction is created by cold welding and galling that occur on the punch surface.

Stripping force is generally expressed as a percentage of the force required to punch the hole. This percentage greatly changes with the type of material being punched and with the amount of clearance between the cutting edges (Fig. 7). Figure 8 presents graphs showing the effects of these two conditions.

The surface finish of the punch changes with the number of holes being punched, and if a lubricant is not used, the effect of punch finish can be very severe, as shown in Fig. 9. The upper curve shows that dry punching produces a stripping force after seven holes of 25% of the punching force. After seven holes, the surface of the punch smoothens and the force drops. (Figure 10 shows the punch after each hole.)

A good grade of die-cutting lubricant substantially reduces the stripping force, as shown in Fig. 9 (lower curve).

Stripping (Fig. 11) can be accomplished with a spring-loaded (urethane or die rubber) plate that holds the material firmly against the die or a positive stripper plate that is set a short distance above the material. With a positive stripper, the material is lifted with the ascending punch until it contacts the stripper and is freed of the punch.

## Shearing Force

The formula for the force  $F$  (area times shearing stress) required to shear, blank, or

punch a given material, assuming there is no shear on the punch or die, is:

$$F = LTS \text{ (for any shape cut)}$$

$$F = DTS \text{ (for round holes)}$$

where  $L$  is sheared length, in inches;  $T$  is material thickness, in inches;  $S$  is shear strength of material, in pounds per square inch; and  $D$  is diameter, in inches.

The shear strength of the material, in pounds per square inch, is used, and values for some materials can be found in Table 2. This represents the force required to shear or cut a 25.4 mm (1 in.) square bar of metal (Fig. 12). The same rule is applied to bars of various shapes and for punching and blanking, as shown. For punching and blanking, the perimeter of cut is multiplied by the thickness of the material to find the area (Fig. 13). Note in Table 2 that the shear and tensile strengths are not the same. Also, the yield strength of a material cannot be used for shear strength, because they are not the same. If the shear strength of a material is not given or known, it can be calculated by conducting a simple test on a hydraulic press by punching a hole.

The tonnages required for punching or blanking round holes in mild steel plate of various thicknesses are presented in Table 3 for convenience. For example, punching a 12.7 mm ( $1/2$  in.) diameter hole through 6.4 mm ( $1/4$  in.) thick mild steel requires 9.8 tons. Table 3 can also be used for determining tonnages for other materials by multiplying the value in the table by the chart multiplier given in Table 2 for the material in question. For example, the chart multiplier for aluminum alloy 6061-T6 is 0.58, which means that its shear strength is 58% of that for mild steel. Thus, punching a 12.7 mm ( $1/2$  in.) diameter hole through 6.4 mm ( $1/4$  in.) thick 6061-T6 would require  $9.8 \times 0.58$ , or 5.68 tons. Tonnage requirements for punching holes greater than 25.4 mm (1 in.) in diameter can be calculated by adding the tonnages for two or more diameters, the total of which equals the desired diameter. For example, the tonnage required for punching a 38.1 mm ( $1\frac{1}{2}$  in.) diameter hole through 6.4 mm ( $1/4$  in.) thick

Fig. 7 Variation of stripping force with clearance

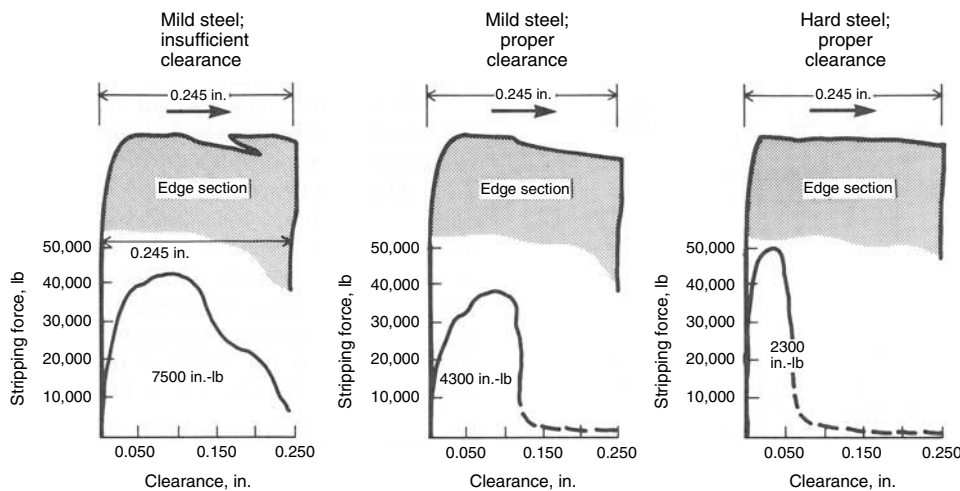

Fig. 8 Force curves showing effects of clearance and material hardness

Fig. 9 Variation of stripping force with lubrication and number of holes. Mild steel, 12.7 mm ( $1/2$  in.) thick; punch diameter, 15.2 mm (0.600 in.); 10% overall clearance

mild steel would be the sum of the tonnages for punching a 12.7 mm (1/2 in.) diameter hole and a 25.4 mm (1 in.) diameter hole through 6.4 mm (1/4 in.) thick plate, or  $9.8 + 19.7 = 29.5$  tons.

There are times when the shear strength of a material is unknown but the tensile strength is known. In such instances, the shear strength can be estimated by taking a percentage of the tensile strength, but this percentage varies with the type and thickness of the material. Figure 14 gives percentages found by sampling three types of material.

**Effect of Clearance on Force and Power Requirements.** Clearance has little or no effect

Fig. 10 Galling on surface of punch after punching each of ten holes

Fig. 11 Stripping with spring-loaded and positive stripper plates

on the amount of force required for shearing or punching, provided there is no shear on the blades, punch, or die. Many studies have been conducted to support this theory, and the results of one are given in Fig. 15. The two curves represent mild steel of equal thickness, one with insufficient clearance and the other with proper clearance. The heights of these two curves are approximately the same, the one for insufficient clearance being slightly higher.

The areas under the curves represent the power requirements. Insufficient clearance greatly increases the work requirement (850 J, or 7500 in.·lbf, compared with 485 J, or 4300 in.·lbf) as a result of the secondary shear. With insufficient clearance the shearing force is present throughout the material thickness, whereas with proper clearance, the force drops off approximately halfway through the material. It is quite obvious at this point why tool life is shortened by insufficient clearance—the tool performs 75% more work.

**Reducing Shear Forces.** A progressive shearing action is commonly used to reduce the required force. This is accomplished by stepping or staggering of punches where more than one

punch is used so that they do not cut at the same time, or by grinding an angle on the punch and die edges. In both methods, the work is done over a greater distance with less force, but the total work performed is the same as if there were no stepping or shear on the punches.

Figure 16 illustrates three punches, each stepped equal to half the material thickness. With proper clearance, in punching of mild steel, the maximum force required would be that required for just one punch. The work curve at the top of the figure shows the maximum force plus the fact that three times as much energy must be delivered from the flywheel of a mechanical press, which can be a problem for some presses. Most hydraulic presses deliver full tonnage throughout the stroke with sufficient energy.

Table 2 Average ultimate strengths of selected materials

Chart multiplier: Values in chart are for plate with a shear strength of 50,000 psi. For punching of materials with different shear strengths, it is necessary to use a multiplier (Table 2) for calculating the proper amount of force required to punch the hole. Example: To calculate the required force for punching a 1 5/16 in. diam hole through ASTM A-36 steel (60,000 psi shear strength) 1 in. thick, multiply 73.8 tons by the multiplier for A-36 (1.20) to arrive at 73.8 × 1.20 = 88.6 tons. Recommended press size, 96 ton series.

**Fig. 15** Variation of work requirement (area under curve) with clearance**Fig. 17** Effect of punch-face shear on punching force

If the die clearance for punching the three holes were insufficient, the maximum required force would be greatly affected, as shown by the dotted curve. The force requirement of one punch must diminish before the next punch contacts the material. (Figure 15 illustrates the problem of insufficient clearance.)

**Fig. 18** Effect of clearance on force required for punching with sheared tooling. Force  $F$  varies with cutting length  $L$ ;  $L$  depends on clearance and on the type and hardness of material.

Calculating the effect of applying a shear angle to the face of a punch is difficult due to many variables. Figure 17 shows the effect of shear angle as related to the thickness of material being punched. For example, if the punch has an  $R$  (as defined in Fig. 17) of 6.4 mm (1/4 in.) and the thickness ( $T$ ) of the material being punched is

**Fig. 14** Relationship of shear strength to tensile strength**Fig. 16** Stepped punches

6.4 mm (1/4 in.), the calculated punching force using the formula in Fig. 13 would be reduced by 40%.

The effect of shear shown in Fig. 17 holds true only if a 15% overall clearance is used. Less clearance increases the area being sheared, as shown in Fig. 18. Insufficient clearance can increase the punching force by as much as 50%.

An example of the necessity for proper clearance is where a 30 ton hydraulic press will punch a 51 mm (2 in.) diameter hole through 6.4 mm (1/4 in.) thick mild steel with a punch having a 3.2 mm (1/8 in.) shear (1/2  $T$ ). However, with insufficient clearance, the required tonnage approaches the full tonnage for that of a punch and die without shear (40 ton), and the 30 ton press will not do the job. A die 0.79 mm (1/32 in.) larger than the punch should be used in this case to provide proper clearance.

There are many ways of applying shear to a blade, punch, and die. The standard practice on a squaring shear is to have the blade inclined from one side to the other, normally at a rate of 0.3 mm/cm (3/8 in. per foot). Figure 19 illustrates various methods of applying shear to the punch and die. It is important to maintain balanced loading of the punch and die to prevent side thrusts on the punch that would cause the punch to crowd over and hit the die. This is the same

problem encountered in punching part of a hole at the edge of a sheet.

Use of shear on a punch and die is an inexpensive way of stretching press capacity, provided the press has sufficient energy to accept the additional work. Many mechanical (flywheel-type) presses do not have sufficient energy to take advantage of shear. In fact, shear can decrease capacity if not properly applied.

## Diameter-to-Thickness Ratios

Very small holes cannot be punched through very thick material—for example, a 6.4 mm ( $1/4$  in.) diameter hole through 25.4 mm (1 in.) thick mild steel. In this case, the hole would have to be drilled, but where is the limiting point?

The old rule of thumb that the punch diameter must be at least equal to the thickness of the material has cost industry thousands of dollars. One steel fabricator had the architect increase the hole diameter specification from 20.6 to 23.8 mm ( $13/16$  to  $15/16$  in.) so he could punch several thousand holes in 25.4 mm (1 in.) thick beams. He consented to pay the extra cost for larger fasteners, which was far less than the cost of drilling. Unfortunately, he did not know that with his portable press he could punch 20.6 mm ( $13/16$  in.) diameter holes through 25.4 mm (1 in.) thick mild steel consistently.

When all the factors involved in the thickness-diameter ratio limitation are considered, it is possible to come up with a new, more realistic set of ratios for nonshock applications.

The diameter of the punch must be such that the punch compressive strength is greater than the force required to punch the hole. This punching force can be found by multiplying the material thickness by its shear strength (in pounds per square inch), then multiplying by the length of cut.

To determine if a punch will endure when used in a hydraulic press, the following factors must be considered:

- $A$  = Cross-sectional area of the punch, as determined by hole size and shape (Fig. 20)
- $T$  = Thickness of material being punched
- $S_s$  = Shear strength of material being punched

Fig. 19 Methods of applying shear to punches and dies

- $S_c$  = Compressive stress in the punch
- $L$  = Length of cut

The compressive stress in the punch can be calculated from the formula:

$$S_c = \frac{T \times S_s \times L}{A}$$

The maximum allowable compressive stress ( $S_c$ ) depends on the type and hardness of the tool steel from which the punch is made. A good grade of oil-hardened shock-resistant tool steel will withstand a compressive stress of 300,000 psi before breaking and can be used safely at 250,000 psi with good tool life.

The curves in Fig. 21 are based on these punching strength values, and for a known shear strength (of the material being punched), the curves give the recommended thickness-to-diameter ratio.

The curve shown as a dotted line represents the ultimate strength (300,000 psi); the solid curve, the recommended working stress (250,000 psi). For example, for punching of mild steel with a shear strength of 50,000 psi, the recommended thickness-to-diameter ratio is  $1\frac{1}{4}$  to 1; the ultimate ratio is  $1\frac{1}{2}$  to 1. Therefore, it is safe to punch a 25.4 mm (1 in.) diameter hole through 31.8 mm ( $1\frac{1}{4}$  in.) thick mild steel.

Quite often, a ratio between  $1\frac{1}{4}$  and  $1\frac{1}{2}$  to 1 is used for mild steel, but punch life is shortened.

**Minimum Hole Size.** The graph in Fig. 22 shows the minimum diameter of hole that can be punched through a given thickness of material. Three different materials are illustrated.

To use this graph, locate the thickness of material along the vertical scale and follow across horizontally to the lower edge of the indicated area for the material being punched. From this point of intersection, drop down to the horizontal scale and read the minimum recommended hole diameter.

The upper edge of the indicated area for each material represents the breaking point for the punch. Working within the indicated areas will therefore result in shortened punch life. For example, in punching 19 mm ( $3/4$  in.) thick mild

Fig. 20 Relationship of punch diameter to material thickness

steel, 15.1 mm ( $19/32$  in.) is the recommended minimum hole diameter; if a 12.7 mm ( $1/2$  in.) diameter punch is used, it will fail.

A punch will fail in one of two ways when overloaded. If its elastic limit is slightly exceeded, the punch will expand as it is pushed through the material. A very high force is then required during stripping, causing the punch to break either at the punch end or under the head.

The second type of failure occurs when the compressive stress is greatly exceeded, and the punch simply buckles before penetrating the material.

Special guided punches (Fig. 23) are available for piercing material up to 12.7 mm ( $1/2$  in.) thick; these punches are supported to prevent buckling and offer thickness-to-diameter ratios as high as 2 to 1 in mild steel.

## Limitations of Punching

Punching can cause distortion. In some parts, there is nothing that can be done to overcome it, but in many cases, steps can be taken to minimize it.

One common problem is the closeness of a hole to the edge of a part, which, if too close, causes bulging along the edge. Preferably, two times the thickness of the material should be allowed from the edge of the hole to the edge of the part.

Another frequent problem that occurs on strip and bar stock is camber due to off-center punching—for example, punching a row of 24 mm ( $15/16$  in.) diameter holes on 75 mm (3 in.) centers in a 150 mm (6 in.) wide, 20 mm ( $3/4$  in.) thick bar of mild steel where the common centerline is 50 mm (2 in.) in from one side. Figure 24 shows the type of distortion that will result. The holes should be on-center where possible, and the bar should not be too narrow. Insufficient clearance will cause increased distortion, due to the increased outward forces produced.

## Die Clearances and Stripping Forces

**Relationship of Die Clearance to Stress-Strain Curves.** One of the most important

Fig. 21 Ratio of material thickness to punch diameter as a function of shear strength

Fig. 22 Minimum punch diameter (hole size) as a function of material thickness

Fig. 24 Distortion resulting from off-center punching

factors in the design of punches and dies is the amount of clearance necessary between the punch and die. The amount of clearance, to a great extent, determines the life of the die, the interval of time between successive sharpenings of the die and punch, the quality of the work being sheared or stamped, the power requirements for the punch press producing the work, and the stresses built up in the press during a cycle. Die clearance varies with the thickness, type, hardness, and complexity of the work. No exact information giving the correct amount of die clearance for a set of known conditions is available. The determination of die clearance has been largely a matter of guesswork and rule-of-thumb procedures.

The subject of die clearance and its many aspects covers an extremely large field, and

prolonged and varied investigations have been necessary to give complete explanation to the variety of phenomena involved. One example is data acquisition directed toward investigation of instrumentation for die clearance studies conducted at Purdue University, as described here by Lascoe (Ref 1). A stress-strain indicator was used to record two electrical input signals plotting the force applied to the material and the distance through which the punch progressed. By examination of the load curve—that is, a plot of force applied versus the position of the punch—it was possible to determine the dynamic properties of the metal being worked at that particular clearance (Fig. 25). By analyzing a series of load curves resulting from the use of different die clearances, an accurate determination of the optimal die clearance for a given set of

Fig. 23 Guided punch. Courtesy of Durable Punch and Die Company

Fig. 25 Key for interpreting plot of loads from punching tests

Fig. 26 Distance of punch travel through 3.2 mm ( $1/8$  in.) thick flat naval brass stock (hardness, 62 HRB) for complete severance

conditions was made (Fig. 26, 27). The stress-strain indicator produces voltages that, when applied to an electronic display or digital recording, plot the load curve. Strain gages and a differential transformer were used as the input transducers.

The purpose of this study was to investigate the possibility, usefulness, and reliability of such

an electronic approach to the accurate determination of optimal die clearances. The investigation was of a general nature in which various types of metals and clearances were used. The oscilloscope traces of the load curves were then

**Fig. 27** Distance of punch travel through 3.2 mm ( $1/8$  in.) thick flat aluminum stock (hardness, 73 HRB) for complete severance

**Fig. 28** Maximum force required for blanking a 25.4 mm (1 in.) diameter slug from 3.2 mm ( $1/8$  in.) thick flat naval brass stock (hardness, 62 HRB)

analyzed for possible analytical relationships between die clearance and maximum force required to stamp out the work, work required to sever the part, amount of "dish" of the resulting work, and the distance of travel of the punch through the metal stock before complete severance occurred. From this study it was established that die clearance definitely affects the aforementioned factors and that such an electronic approach to the determination of an optimal die clearance for a given set of conditions is practical and useful.

**Interpretation of Stress-Strain Curves.** The functioning of a great many blanking dies may be likened to a tensile test for determining physical properties of a material; that is, the material is stressed at a concentrated point until rupture

occurs. The pattern of this rupture—stress versus strain—closely approaches that of a metal slug being separated from its "mother" sheet by means of a blanking operation. The resulting stress-strain curve provides a wealth of information. The explanation of the procedure is in interpreting the stress-strain curves:

- The integral of the curve represents the work required to blank out the slug. When the vertical displacement conversion factor to stress and the horizontal conversion factor to strain are known, the areas under the curve can be determined and the work determined directly.
- The maximum height of the curve represents the maximum amount of force required to sever the blank from the sheet. The vertical-displacement calibration factor is known because the press ram can be calibrated on a materials testing machine (refer to Fig. 25).

**Fig. 29** Maximum force required for blanking a 25.4 mm (1 in.) diameter slug from 3.2 mm ( $1/8$  in.) thick flat stainless steel stock (hardness, 85 HRB)

Hardness: 65 HRB. Thickness of metal strip: 3.25 mm (0.128 in.). (c) Cold rolled steel. Hardness: 93 HRB. Thickness of metal strip: 3.0 mm (0.118 in.). (d) SAE 1020 cold rolled steel. Hardness: 99 HRB. Thickness of metal strip: 3.18 mm (0.125 in.).

- The amounts of secondary and tertiary shear can be determined from the areas under the second and third peaks, respectively.
  - The differential of the curve at any point indicates the rate of change in the loading or unloading force at that time. If the curve is approaching the vertical, it means that the loading is applied almost instantaneously without any appreciable plastic deformation in the blanked slug, whereas a gradually sloping curve indicates plastic deformation or burring.
  - Likewise, if the curve drops off almost vertically, it means that the severed piece has been cut "clean." If the dropoff is gradual, it means that a number of shear lines have overlapped each other and that, when the complete breakthrough does occur, the resulting cut is rough and ragged.
  - The point at which the trace dips down to or below the datum line is the point of breakthrough or sudden load reversal, as was the case with aluminum. In some instances, the propagation of a crack will move faster than the punch, causing the trace to fall below the datum line even though the piece has not been completely severed.
  - Any forces indicated beyond the horizontal distance representing the metal thickness are caused by the resistance of the slugs to movement between the die walls.
- Results.** The results of this test were highly satisfactory from the standpoint of a visual graphical record of the data secured. The data showed a definite relationship between the die clearances and the dynamic characteristics of the materials being tested. Perhaps the major

contribution of this investigation was to prove that the dynamic properties of metals are much different from the static properties in many instances. One author states that press-tonnage requirements are estimated by using dies with sharp edges and that the maximum pressure normally required equals the area adjacent to the perimeter of the cut. This is true for static conditions but is not applicable to dynamic conditions. Examination of the force-versus-die-clearance curve indicated that the dynamic force required for blanking is approximately 20 to 25% above the static force necessary to blank the same type and thickness of metal. This excessive amount of force required for blanking was apparent in all the metals used.

An increase in die clearance up to 8 to 12% gave work curves that showed a decided decrease in the amount of work required for blanking. A clearance below 6%, for 3 mm ( $1/8$  in.) material, generally indicated excessive tool wear and excessive stresses in the press.

The nature of the blanked edge depended on the clearance. As clearance increases, the finish or quality of the blanked edge increased up to approximately 6 to 10%. Then plastic deformation occurs.

The "dish" deformation of the blanked slug tends to increase with increasing clearance. Dishing is much more prevalent in the softer materials; consequently, die clearance is more critical for softer metals. Die clearance has to be large enough to reduce work and dynamic forces, yet small enough to allow the product to fall within acceptable dish specifications. Die clearance can be excessive for the harder materials because of their ability to withstand dishing.

Metal hardness is an important factor in determining stress-strain characteristics. Because of the inability of the harder metals to absorb the inertial effects of the punch-press ram, the maximum force required for blanking is higher for harder metals than for softer metals of the same ultimate shearing stress. Figures 28, 29, and 30 show forces versus die clearances for various materials.

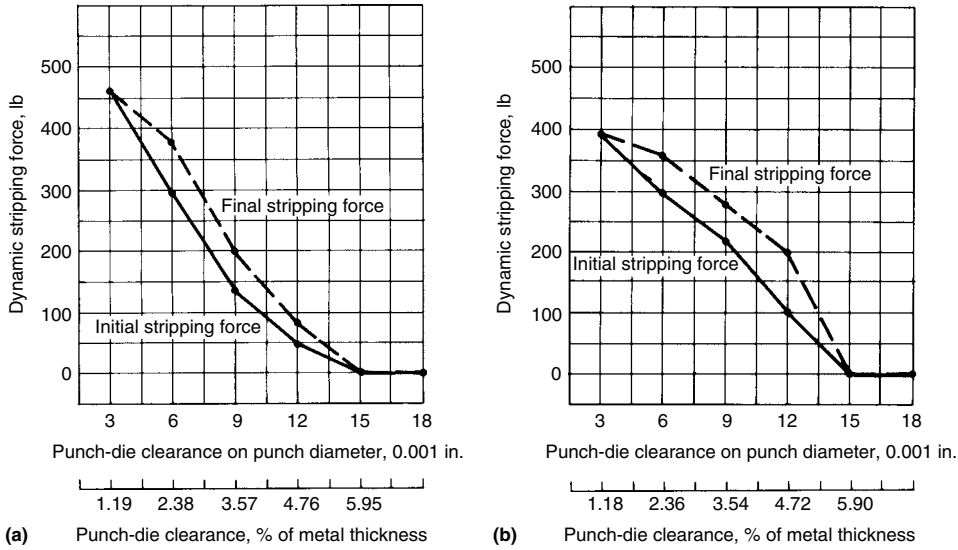

#### Dynamic Stripping Forces in Blanking.

When a hole is punched, the material exerts a radial clamping force on the punch surface, and so a certain amount of force is required to withdraw the punch. This is called the stripping force.

The strength design of the stripper plate, which holds the material down during the upstroke of the punch, is based on the maximum value of the stripping force. Because experience formulas provide only a rough approximation method for the computation of this force, it is advisable to use a large safety factor. It is easy to design the stripper plate to be strong enough to withstand the largest stripping forces that occur.

There is a more important aspect of this force: its characteristics provide important information about the punching condition and about certain influential variables.

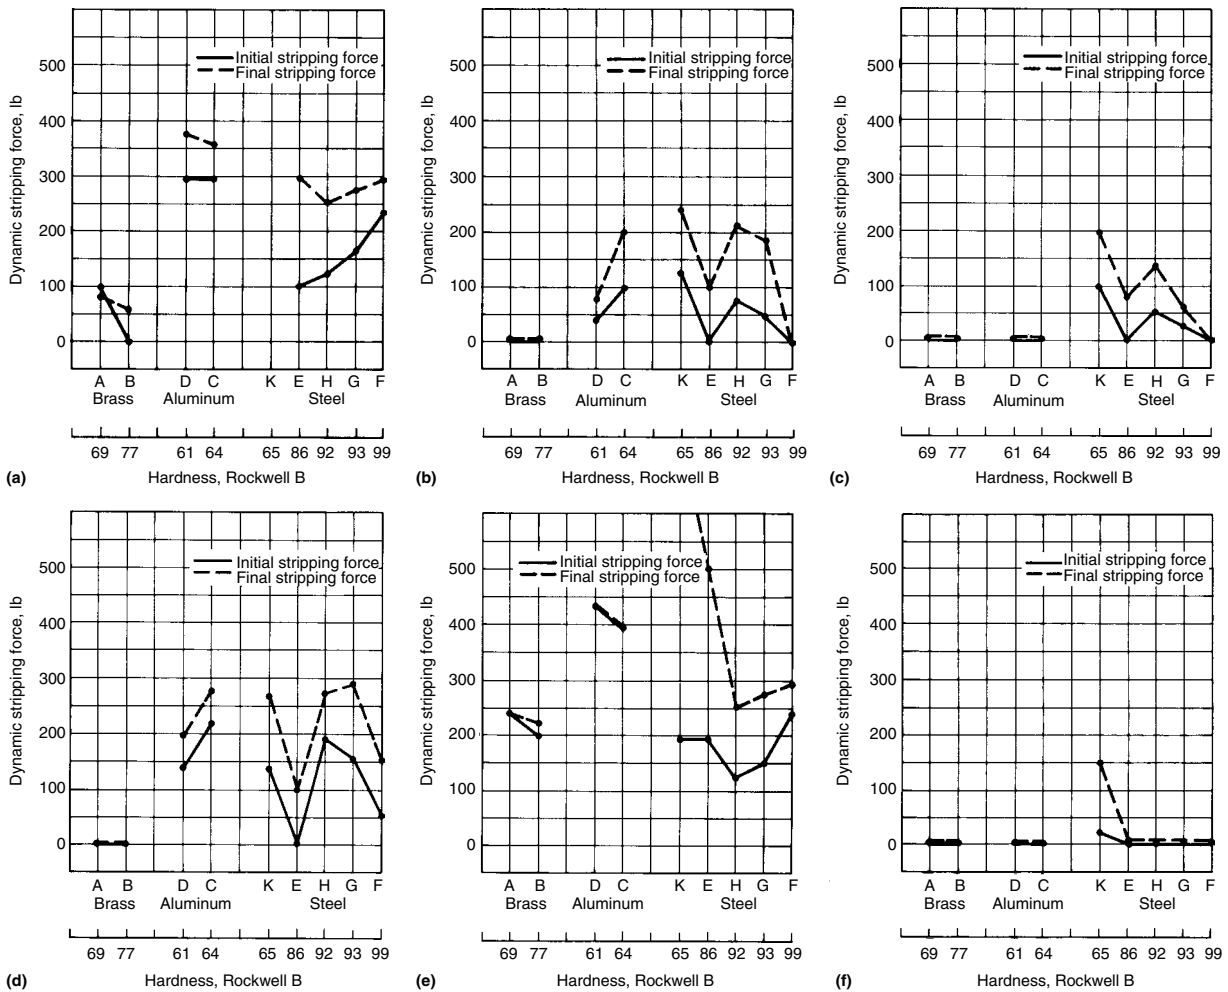

With an electronic recording method it is possible to measure the stripping force under actual operating conditions, thus eliminating the

**Fig. 34** Dynamic stripping force as a function of punch-die clearance. (a) Aluminum 2024-T3. Hardness: 61 HRB. Thickness of metal strip: 3.2 mm (0.126 in.). (b) Aluminum 2024-T. Hardness: 64 HRB. Thickness of metal strip: 3.23 mm (0.127 in.).

(a) Punch-die clearances of 0.152 mm (0.006 in.) on punch diameter and 0.076 mm (0.003 in.) per cutting edge. (b) Punch-die clearances of 0.305 mm (0.012 in.) on punch diameter and 0.244 mm (0.0096 in.) per cutting edge. (c) Punch-die clearances of 0.381 mm (0.015 in.) on punch diameter and 0.191 mm (0.0075 in.) per cutting edge. (d) Punch-die clearances of 0.229 mm (0.009 in.) on punch diameter and 0.114 mm (0.0045 in.) per cutting edge. (e) Punch-die clearances of 0.076 mm (0.003 in.) on punch diameter and 0.038 mm (0.0015 in.) per cutting edge. (f) Punch-die clearances of 0.457 mm (0.018 in.) on punch diameter and 0.244 mm (0.0096 in.) per cutting edge.

approximations of formulas based on experience. This investigation method results in a load curve, which is a plot of what is called the dynamic stripping force versus the position of the punch relative to the material being punched. Electric strain gages attached to the stripper plate record the size of the dynamic stripping force. The horizontal travel of this beam is related to the movement of the punch. This is achieved through a differential transformer with the core bar attached to the ram of the punch press.

The primary purpose of this investigation was to design and build a test setup based on the recording method outlined previously. Its secondary purpose was to perform some limited investigations in order to determine its usefulness and reliability.

Two major investigations were performed:

- For nine different materials, the relation between the dynamic stripping force and the amount of punch-die clearance was established.
- The effect of punch wear on the dynamic stripping force was recorded.

*Results.* The best results indicated a strong dependence of punch load on the amount of punch-die clearance (Fig. 31 to 36). The same was found to be true for punch wear, when it is caused by material buildup near the cutting edge of the punch. Several points are also worthy of consideration:

- A rectangular shape of the load curve for the dynamic stripping force indicates a favorable punching condition. The more triangular the form of the curve becomes, the more material buildup occurs near the cutting edge of the punch, and the worse the general punching condition.
- The characteristics of the insides of the holes are directly related to the size of the dynamic stripping force. It is possible to develop theoretical explanations for most of the characteristics of the dynamic stripping force.

- A microscopic analysis of the area near the cutting edge of the punch reveals interesting aspects of punch wear. If this wear is caused by material buildup near the cutting edge, then the load curve clearly shows this condition with an increase of the terminal stripping force values.
- A tentative theory can be developed that provides an explanation for the material buildup near the cutting edge of the punch.

# Shearing of Sheet, Strip, and Plate

Revised by L. Chen, Engineered Materials Solutions, Inc.

**SHEARING** is a method for cutting a material piece into smaller pieces using a shear knife to force the material past an opposition shear knife in a progression form. Shearing is widely used to divide large, flat stock such as sheet, strip, and plate. Shearing of sheet, strip, and plate is broadly classified according to the type of blade (knife or cutter) used as either straight or rotary. Straight-knife shearing is used for squaring and cutting flat stock to the required shape and size. It is usually used for producing square and rectangular shapes, although triangles and other straight-sided shapes are also sheared with straight knives. Rotary shearing (which should not be confused with slitting, as discussed in the article "Flattening, Leveling, Slitting, and Shearing of Coiled Product" in this Volume) is used for producing circular or other contoured shapes.

## Straight-Knife Shearing

In straight-knife shearing, the flat workpiece is placed between a stationary lower knife and a movable upper knife. As the upper knife is forced downward, it cuts the metal into two parts. Straight-knife shearing is the most economical method of cutting straight-sided blanks from flat sheet, strip, and plate with thickness no more than 50 mm (2 in.). The process is also widely used for cutting sheet into blanks that will subsequently be formed or drawn. Because shear gaging can be set within  $\pm 0.13$  mm ( $\pm 0.005$  in.), the shearing process is generally limited to  $\pm 0.4$  mm ( $\pm 1/64$  in.) tolerances in 16 gage material. The tolerance range increases with thickness.

Straight-knife shearing is seldom used for shearing metal harder than approximately 40 HRC. As the hardness of the work metal increases, knife life decreases for shearing a given thickness of metal. In general, it is practical to shear flat stock up to 38 mm (1½ in.) thick in a squaring shear. Squaring shears up to 9 m (30 ft) long are available (even longer shears have been built), and some types are equipped with a gap that permits shearing of metal longer than the shear knife. When extremely soft, ductile metal (especially thin

sheet) is sheared, the edges of the metal roll, and large burrs result.

## Principle of Shearing

The principle of shearing is simple. When the upper knife is forced to move downward, both the upper and lower knives gradually come together and contact the metal being sheared. The knives penetrate to a certain portion of the metal thickness until its shear strength is reached, at which point the unpenetrated portion of the metal fractures, and the work metal separates (Fig. 1). At the final stage of shearing, the upper knife continuously moves downward and results in freeing the sheared pieces from the original workpiece. The upper knife wall rubs against the metal edge to cause the cutting edge area to burnish, while the lower knife wall rubs against the sheared piece edge to cause a second burnish area. A burr occurs on both the sheared piece and the original workpiece. The amount of penetration depends largely on the shear strength and thickness of the work metal. The knife will penetrate 30 to 60% of the metal thickness for low-carbon steel, depending on thickness (see the section "Capacity" in this article). The penetration will be greater for a more ductile metal such as copper. Conversely, the penetration will be less for metals that are harder than low-carbon steel.

A sheared edge is characterized by the smoothness of the penetrated portion and the relative roughness of the fractured portion. Sheared edges do not have the quality of machined edges. However, when knives are kept sharp and in proper adjustment, it is possible to obtain sheared edges acceptable for a wide range of applications. The quality of sheared edges generally improves as workpiece thickness decreases.

## Machines for Straight-Knife Shearing

Punch presses and press brakes can be used for shearing a few pieces or are used temporarily when more efficient equipment is not available. Production shearing, however, is usually done in machines that are designed for this operation.

**Squaring shears** are usually used for trimming and cutting sheet, strip, or plate to specific size (Fig. 2). These shears (also called resquaring or guillotine shears) are available in a wide range of sizes and designs. Some types of lines also permit slitting when the workpiece moves for shearing.

The sheet, strip, or plate is held firmly by hold-down devices while the upper knife moves down past the lower knife. Most sheet or plate is sheared by setting the upper knife at an angle (Fig. 1a). The position of one of the knives can be adjusted to maintain optimal clearance between the knives. Squaring shears can be actuated mechanically, hydraulically, or pneumatically.

**Mechanical Shears.** The power train of a mechanical shear consists of a motor, the flywheel, a worm shaft that is gear driven by a flywheel, a clutch that connects the worm gear drive to the driven shaft, and a ram actuated by the driven shaft through eccentrics and connecting links. Under most operating conditions, a mechanical shear can deliver more strokes per minute (spm) than a hydraulic shear. Some mechanical shears cycle as fast as 100 spm.

Another advantage of the mechanical shear is that, because of the energy stored in the flywheel, a smaller motor can be used for intermittent shearing. For example, a mechanical shear with a no-cutting or free-running speed of 65 spm can make approximately six full shearing strokes (i.e., shearing maximum thickness and length of cut) per minute with a standard motor. However, when the same shear is cutting at full capacity in a rapid shear mode, a much larger motor is required, because in rapid cutting, there is not enough time between cuts for the smaller motor to restore the speed of the flywheel.

An additional advantage of the mechanical shear is that its moving knife travels faster than the moving knife of a hydraulic shear. In some cases, greater knife speed can decrease work metal twist, bow, and camber.

Most mechanical shears are provided with enough horsepower to build up the flywheel speed after each cut but not enough to allow the operator to run full-capacity cuts in a high-speed mode. It should be noted that some of the mechanical shears are not of the flywheel type; rather, their motor directly drives the shear blade beam to move down to make a cut. Mechanical

**Fig. 1** Schematic illustration of straight-knife shearing. (a) Side view. (b) Rake angle

**Fig. 2** Typical squaring shear. Courtesy of Cincinnati Inc.

shears are rated in strokes per minute, not cuts per minute. Most shearing applications do not require high-speed cutting.

**Hydraulic shears** are actuated by a motor-driven pump that forces oil into a cylinder against a piston; the movement of the piston energizes the ram holding the upper knife. A hydraulic shear can make longer strokes than a mechanical shear. In general, long shears and shears with low-carbon steel capacities above 13 mm ( $\frac{1}{2}$  in.) are almost all hydraulic. Hydraulic shears are designed with a fixed load capacity. This prevents the operator from shearing material that exceeds capacity and, therefore, saves costly damage to the machine structure; this is a basic advantage of hydraulic shears.

The total load during shearing is related to the shear knife rake angle, sharpness of the knives, knife clearance and type, and the mechanical

properties and thickness of the material being sheared. It is possible to stall the machine during shearing within a rated capacity if the clearance is incorrect, the knife is dull, or the back piece is excessively deep. In this way, the hydraulic shear is protected from damage caused by overloading. A mechanical shear would not be constrained by an overload prevention system and would continue to cut under nearly all conditions.

**Pneumatic shears** are used almost exclusively for shearing thin metal (seldom thicker than 1.50 mm, or 0.060 in.) in relatively short pieces (seldom longer than 1.5 m, or 5 ft). Activation of air cylinders makes the shear blade beam move to make a cut. Shop compressed air or a freestanding air compressor is used to provide power to air cylinders.

**Alligator shears** have a shearing action similar to that of a pair of scissors. The lower knife is stationary, and the upper knife, held

securely in an arm, moves in an arc around a fulcrum pin. This type of machine is most widely used for shearing bars and bar sections and for preparing scrap. Alligator shears are available in various sizes, including those that can shear plate up to 32 mm ( $1\frac{1}{4}$  in.) thick by 760 mm (30 in.) long and plate up to 50 mm (2 in.) thick in shorter lengths. The lighter machines can be made portable; the heavier machines, however, must be firmly anchored in concrete, especially if they will be used in conjunction with roller conveyor tables in the shearing of plate.

### Accessory Equipment for Straight-Knife Shearing

Some accessories have been incorporated into most shear designs and are required for efficient and accurate straight-knife shearing.

**Holddowns** (Fig. 1a) are mechanical or hydraulic devices that hold the work metal firmly in position to prevent movement during shearing. The holddown pressure must be greater than the forces generated in cutting the work material. These forces depend on the knife clearance, rake angle, and depth of material back piece. The most efficient holddown system is a series of independent units that securely clamp stock of varying thickness automatically and without adjustment. The force on each holddown foot must be substantial, ranging from several hundred pounds on a machine for shearing sheet to several tons for shearing plate. Holddowns must be timed automatically with the ram stroke, so that they clamp the work metal securely before the knife makes contact and release their hold instantly after shearing is completed.

**Back gages** are adjustable stops that permit reproducibility of dimensions of sheared workpieces in a production run. Most gages are controlled electrically. Push-button control provides a selection of high traverse speeds and slow locating movements for accurate final positioning. The addition of a computer numerical

control system permits dimensional accuracy and repeatability, increased productivity, and hands-off safe operations.

For thin sheet, magnetic overhead rollers eliminate sag and support the sheet for accurate gaging. For rapid and accurate cutting, back gages are equipped with electronic sensors that automatically trip the shear only when the sheet is accurately positioned.

Pneumatic supports are used to support thin sheet. Support arms are designed to elevate into a horizontal position that is flush with the shear table, permitting material to be supported in the correct position against the back-gage stop. Blank inaccuracies due to unsupported and poorly positioned sheets are virtually eliminated.

Back gages are also equipped with retractable stops for shearing mill plate. With the stops out of the way, mill plate of almost any length can be fed into the shear and cut to the desired length. When stops are not used, the workpiece can be notched or scribed to indicate the cutoff position.

**Front Gages.** When gaging from the front of the machine, the operator locates the work metal by means of stops secured in the table or in the front support arms. Power operation of the front support arms allows the blank dimensions to be entered digitally using a computer control. Front gaging is often done by means of a squaring arm.

**Squaring arms** (Fig. 3) are extensions attached to the entrance side of a shearing machine that are used to locate long sections of work metal in the proper position for shearing. Each arm is provided with a linear scale and with stops for accurate, consistent positioning of the work metal. Squaring arms are reversible to allow use of the shear at either end and to more evenly distribute the wear on the shear knives. Power operation can be added to the squaring arm for increasing blank accuracy and reducing setup time. This type of squaring arm prevents the arm from moving from side to side.

### Straight Shear Knives

**Material used for shear knives** depends on specific shearing operations. Most shear knives

are made in one piece from tool steel; some are made of carbon or alloy steel. The composition, hardness, thickness, and quantity of metal being sheared are the most important factors in the selection of knife material. An AISI D2 tool steel is often recommended for cold shearing metals up to 6.4 mm ( $1/4$  in.) thick (Table 1). Knives made of modified A8, H13, or S5 tool steels are recommended for low-volume production or for occasional shearing of metals up to 6.4 mm ( $1/4$  in.) thick (except the more highly abrasive metals such as silicon steel). Knives made of A2 tool steel have been satisfactory for high-production cold shearing of soft nonferrous metals. However, D2 knives are usually more economical because of better wear resistance, but they are not usually recommended for cold shearing materials more than 6.4 mm ( $1/4$  in.) thick because they are likely to break under impact loads. Nevertheless, depending mainly on knife design and length of cut, knives made of D2 tool steel have been successfully used for cold shearing aluminum alloys up to 32 mm ( $1 1/4$  in.) thick.

Modified A8 or H13 tool steels are suitable for some cold-shearing applications in which the work metal is more than 6.4 mm ( $1/4$  in.) thick, as indicated in Table 1. However, the shock-resistant grades S2 and S5 are usually recommended for shearing heavy sections of all metals.

The length and design of the knife can influence the selection of knife material. Although water-hardened tool steels such as W1 and W2 are suitable for many cold-shearing applications, the rapid cooling during heat treatment causes greater distortion than that in knives made from the oil-hardened or air-hardened steels such as D2. For example, a bar 4.17 m (164 in.) long is needed to make a shear knife 4.16 m (164 in.) long from D2 tool steel. The same knife made from W2 requires a bar 4.17 m (164 in.) long. Both steels elongate when heat treated, but W2 will bow more readily than D2. Because straightening is difficult, the W2 knife therefore must have more grinding stock. The additional grinding decreases the depth of the hardened shell and shortens the useful life of the knife.

**Hardness.** The rate at which a knife wears in cold shearing depends primarily on its carbon content, alloy content, and hardness. Insufficient hardness in a knife used for cold shearing will shorten its service life. In one application, a knife made of S5 tool steel with a hardness of 44 HRC wore three times as fast as one with a hardness of 54 HRC used under the same conditions. Despite the desirability of having shear knives as hard as possible to minimize wear, it is often necessary to sacrifice some hardness to prevent knife breakage as the hardness or thickness of the metal being sheared increases.

Hardness alone does not always guarantee knife performance and life, because different wear resistance, ductility, or toughness can be obtained at the same hardness. Improper quenching and tempering can result in a unsuitable microstructure and thus insufficient wear resistance, ductility, or toughness for a specific shearing application even though the steel may have the same hardness as obtained in the same steel from proper processes.

Recommendations for the hardness of knives for cold shearing cannot always be made without knowledge of the details of the shearing operations. Such details include type, mechanical properties, and thickness range of the material to be sheared as well as shearing speed and knife dimensions. For example, knives made of D2 tool steel have often been successfully used at 58 to 60 HRC for shearing low-carbon steel up to 6.3 mm ( $1/4$  in.) thick. However, the hardness of a D2 knife must be kept below 58 HRC to prevent knife break if the material to be sheared is high-strength low-alloy steel. The shock-resistant S-grade tool steels are used in the hardness range between 50 and 58 HRC. The hardness of the knives should be decreased from the higher end of the range to the lower end when the hardness or thickness of the materials to be sheared increases. The higher end of this range is applicable to shearing of steels 6.4 to 13 mm ( $1/4$  to  $1/2$  in.) thick and to nonferrous metals. As shock loading increases with the shearing of harder or thicker metals, knife hardness is decreased toward the low end of the aforementioned hardness range.

(a) S5 is preferred for stock thicker than 19 mm ( $3/4$  in.) (b) Seldom sheared thicker than 12.7 mm ( $1/2$  in.)

## Operating Parameters

**Capacity.** Most shearing machines are rated according to the section size of low-carbon steel they can cut. The tensile strength of low-carbon steel sheet and plate is generally below 520 MPa (75 ksi) and the yield strength below 350 MPa (51 ksi). Shears are frequently rated in terms of their ability to cut low-carbon steel with a tensile strength of 415 MPa (60 ksi) and yield strength of 275 MPa (40 ksi). An allowance for normal over-tolerance material thickness is included in the capacity rating of the machine. The use of a machine for shearing other metals is primarily based on the relationship of the tensile strength and ductility of low-carbon steel to that of the particular metal to be sheared. Metals with a tensile strength higher than that of low-carbon steel almost always reduce the capacity of the machine. For example, the machine capacity for shearing high-strength low-alloy steels is reduced to approximately two-thirds to three-quarters of the rated capacity for low-carbon steel. Conversely, for shearing aluminum alloys, machine capacity can range from 1/4 to 1 1/2 times the rated capacity for low-carbon steel.

Table 2 compares the shearing capacities of various metals with those of low-carbon steel. The metal thicknesses given in the table are based on the thickness of low-carbon steel that can be sheared with the same shearing capacity. For example, a specific force is required to shear 6.4 mm (1/4 in.) thick low-carbon steel. Table 2 shows that the same force can shear only a 4.8 mm (3/16 in.) thickness of type 302 stainless steel but can shear a 6.4 mm (1/4 in.) thick aluminum.

Ductility also can affect machine capacity. For example, annealed copper, because of its high elongation, requires as much shearing effort as low-carbon steel, even though copper has considerably lower tensile strength. Similarly, carbon steel with very low carbon (<0.1% C) and higher-than-normal elongation will require a higher-capacity machine.

**Power Requirements.** The energy consumed during shearing is a function of the average stress, the cross-sectional area to be sheared, and the depth of maximum knife penetration at the instant of final fracture of the work metal. For any metal, the amount of energy consumed is thus proportional to the area under the shearing stress-strain curve up to the point of fracture.

Figure 4 shows typical shearing stress-strain curves for hot-rolled and cold-rolled steels. The distance through which the force acts (knife penetration) is approximately 35% of the work metal thickness for hot-rolled steel and 18.5% for cold-rolled steel. For example, in the curve for hot-rolled steel, the average stress under the curve is 73.5% of the maximum shearing stress  $S_{max}$ , and the distance through which the force acts is 35% of the work metal thickness. Therefore, the energy  $E$  used in shearing hot-rolled steel is:

$$E = 0.735 S_{max} \times Wt \times 0.35 t = 0.257 S_{max} \times Wt^2 \quad (\text{Eq 1})$$

where  $W$  is work metal width, and  $t$  is its thickness. Applying Eq 1 to the curve for cold-rolled steel in Fig. 4 yields an energy consumption of  $0.136 S_{max} \times Wt^2$ .

The maximum instantaneous horsepower  $HP_{max}$  required for cutting work metal in a shear is determined by:

$$HP_{max} = \frac{Wt \times S_{max} \times V}{33,000} \quad (\text{Eq 2})$$

where  $V$  is the speed of the shear knife, and the other variables are as previously defined.

The average power requirement  $HP_{avg}$  for a shear making  $n$  cuts per minute in hot-rolled steel is:

$$HP_{avg} = \frac{Wt^2 \times n \times S_{max}}{1,540,000} \quad (\text{Eq 3})$$

Equations 2 and 3 determine the net power required for actual shearing of the workpiece.

The amount of power needed to operate the hold-down system and to overcome friction must be added to net power.

Friction depends on the design of the shearing machine and the knife, type of bearings, alignment, lubrication, temperature of operation, and size of the machine in relation to the area of the section to be sheared. When shearing metal of nearly the maximum size for which a shear is designed, the loss of horsepower by friction for well-designed machines seldom exceeds 25% of the gross horsepower.

**Shearing Force.** It should be noted that the shearing force  $F$  required to cut a piece of metal follows a proportional relationship:

$$F \propto spr^2(1 - p/2)/R \quad (\text{Eq 4})$$

where  $s$  is the shear strength of the metal,  $t$  is the thickness of the material,  $p$  is the percentage of penetration of the knife into the material, and  $R$  is the rake of the shear knife blade.

It is not possible, therefore, to calculate the required shearing force for different work metal thicknesses based solely on change of rake. Even for low-carbon steel, the amount of knife penetration prior to fracture can be as great as 60% of the work metal thickness for 3.4 mm (0.135 in.) thick stock and as little as 30% for 19 mm (3/4 in.) thick stock by the same set of a shear.

**Rake,  $R$ ,** is the tangent of the angle formed between the lower (fixed) shear knife and the upper (movable) shear knife (Fig. 1b). It normally expressed as the upper knife rise per a unit length of the lower knife. For example, a rake of 21 mm/m (1/4 in./ft) means that the upper knife rises 21 mm for each meter (1/4 in. for each foot) of linear distance along the knives. Rakes below 21 mm/m (1/4 in./ft) are rarely used; a rake of 42 mm/m (1/2 in./ft) or higher is typical of many plate shears.

A certain degree of rake is used to permit progressive shearing of the work metal along the length of the knife. As the rake decreases, the amount of upper knife blade engagement increases as it travels through the material; this results in a greater required shearing force. A higher rake reduces the shearing force and

**Table 2 Shearing capacities for various metals compared to those for low-carbon steel**

(a) Also applicable to soft to half-hard strip steel, alclad steel, and copper and copper alloys. (b) Also applies to most other austenitic stainless steels, normalized alloy steels such as 4130 or 8630, annealed high-carbon steels, and annealed tool steels

**Fig. 4** Typical curves of shear stress and shear strain for hot-rolled and cold-rolled steels

allows the use of a smaller machine to shear the material than would be necessary if the cutting edges of the knives were parallel. However, a high rake increases the distortion in the sheared materials. A high rake also can cause slippage and therefore require high hold-down forces. A rake should be as low as possible to reduce the amount of distortion in the sheared materials.

**Knife clearance** is another important parameter; it is the gap between the upper knife and the lower knife as they pass each other. Too tight a clearance will result in secondary fracture after the first fracture, and the cut edge displays a characteristic ragged shape. On the other hand, too much clearance will result in a tear and high burr rather than a clean cut on the cut edge. A more serious consequence of excessive clearance is that it can cause the workpiece to be pulled between the knives. This, in turn, causes overloading of the machine and may result in failure of machine components or shear knives.

The major effects of knife clearance are the appearance of the sheared edge and the squareness of the cut. For example, for annealed mild steel, when sheared edge condition and appearance are critical, the knife clearance is between 4 and 10% of the material thickness. In contrast, it is 9 to 15% when the edge condition and appearance are not critical. The knife clearance also affects the degree of twist of the drop sheet and the shearing force required. Because of knife deflection during shearing in some shears, the clearance at the center of the knife is usually set less than that at the ends. Knife clearance (except on machines using a fixed clearance) is generally increased as work metal thickness increases.

When soft metals are sheared, insufficient clearance causes double (secondary) shearing, which appears as a burnished area at the top and bottom of a sheared edge with a rough area between the burnished edges. Knife clearance usually should be increased as the hardness of the metal being sheared decreases. Some mechanical shears are constructed to operate with a fixed clearance, and no adjustments are made for variations in work metal composition or thickness. The knife clearance is set for the thinnest material to be sheared. If the range of thicknesses sheared is not too large, then double shear may be avoided.

**Ram speed in straight-knife shearing** (and, in turn, the knife speed) has some effect on results in the shearing of flat sheet, strip, and plate. Low linear speed produces a rough sheared edge. As speed is increased, a cleaner sheared edge is obtained. In general, speeds to 21 to 24 m/min (70 to 80 ft/min) can be used without difficulty when shearing annealed metals. Regardless of the speed used, adequate hold-down force is mandatory.

### Shearing Attributes and Defects

**Dimensional accuracy** obtained in straight-knife shearing is influenced by the capacity

and condition of the machine, condition of the knives, knife clearance, and work metal thickness and condition. For example, a total tolerance of 0.25 mm (0.010 in.) usually can be achieved in sheets with a thickness no more than 3.4 mm (0.135 in.) when they are sheared to a size up to 3.7 m (12 ft) long. This tolerance applies to sheets that are essentially free from residual stress and flat within commercial limits. Sheets that are not flat or have residual stress, or both, cannot be sheared with the same accuracy.

Greater tolerances are required in shearing plate. A total tolerance of 0.5 to 1.0 mm (0.020 to 0.040 in.) can be maintained when plate is sheared in squaring shears. Dimensions can be held to a tolerance of approximately  $\pm 1.6$  mm ( $\pm 1/16$  in.) when shearing in alligator shears.

**Sheared edge condition** already has been discussed in this section. In summary, good sheared edge quality needs proper knife sharpness, knife clearance, and sufficiently high ram speed.

**Bow**, or cross bow, is one of three major shape defects introduced in short sheared pieces during shearing (Fig. 5). Bow is nearly proportional to the rake angle of the upper knife when a short piece is being sheared. A high rake causes the materials to bend during shearing. Reducing the rake angle will minimize a bow in a short sheet being cut when the incoming material has a good shape. The bow will become negligible when the sheet being sheared is more than 100 mm (4 in.) long.

**Twist** in a short sheared piece is generally proportional to the rake of the upper knife. Thick plates twist more than thin sheets, if both of them have the same good quality of incoming materials in shape. Soft materials tend to have more twist than hard materials. Wide incoming material has a higher tendency to twist in a short sheared piece than narrow incoming material. Short sheared pieces appear more twisted than long sheared pieces. When 6.4 mm ( $1/4$  in.) plate is sheared, there is some twist in a 25 mm (1 in.) long sheared piece (drop). If the length of the sheared piece increases to 100 mm (4 in.), no twist occurs visually. When 25 mm (1 in.) plate is sheared, the length of the sheared piece must be greater than 125 mm (5 in.) for no measurable twist.

**Camber** cannot be eliminated in short sheared pieces (<100 mm, or 4 in.) but sometimes can be reduced by lowering the rake angle of the upper knife. Sufficient hold-down pressure close to the shear may help reduce camber.

### Rotary Shearing

Rotary shearing, or circle shearing (not to be confused with slitting), is a process for cutting sheet and plate in a straight line or in contours by means of two revolving, tapered circular cutters. Table 3 lists recommended cutter materials.

For conventional cutting to produce a perpendicular edge, the cutters approach each

other and line up vertically at one point (Fig. 6a). The point of cutting is also a pivot point for the workpiece. Because of the round shape of the knives, they offer no obstruction to movement of the workpiece to the right or left. This feature permits the cutting of circles and irregular shapes that have small radii, as well as cutting along straight lines.

Overlapping of the cutters to the position shown in Fig. 6(b) permits the shearing of smooth beveled edges in straight lines or circular shapes. With the cutters positioned as shown in Fig. 6(b), a bevel can be cut across the entire thickness of the workpiece, resulting in a sharp edge on the bottom of the workpiece, or (by varying the overlap of the cutters) only a corner of the workpiece can be sheared off, leaving a vertical edge (or land) for approximately half the workpiece thickness.

The shearing of workpieces into circular blanks requires the use of a holding fixture that permits rotation of the workpiece to generate the desired circle. For straight-line cutting in a rotary shear, a straight-edge fixture is used, mounted in the throat of the machine behind the cutter heads.

**Applicability.** Any metal composition or hardness that can be sheared with straight knives can be sheared with rotary cutters. In general, rotary shearing in commercially available machines is limited to work metal 25 mm (1 in.) thick or less. There is no minimum thickness. For example, wire cloth made from 0.025 mm (0.001 in.) diameter wire can be successfully sheared by the rotary method.

Circles up to 3 m (10 ft) in diameter or larger can be produced by using special clamping equipment. Minimum diameters depend on the thickness of the work metal and the size of the rotary cutters. Typically, with material up to 3.2 mm ( $1/8$  in.) thick, the minimum circle that can normally be cut is 150 mm (6 in.) in diameter. For 6.4 mm ( $1/4$  in.) thick stock, the minimum diameter is 230 mm (9 in.), and for 25 mm (1 in.) thick stock, the minimum diameter is 610 mm (24 in.).

Rotary shearing is limited to cutting one workpiece at a time. As in straight-knife shearing, multiple layers cannot be sheared, because each layer prevents the necessary breakthrough of the preceding workpiece.

Rotary shearing, plasma cutting, laser cutting, waterjet cutting, gas cutting, and electric arc cutting are competitive for some operations (see the article "Cutting Operations" in this Volume). Each can produce straight or beveled edges of comparable accuracy. The selection of one of these processes depends largely on the thickness

**Fig. 5** Three major shape defects introduced by shearing of short sheared pieces

**Table 3 Recommended knife materials for rotary shearing of flat metals**

Metal to be sheared	Thickness to be sheared		
	4.8 mm (3/16 in.) or less	4.8–6.4 mm (3/16–1/4 in.)	6.4 mm (1/4 in.)
Carbon, alloy, and stainless steels	D2(a)	A2(b)	S4; S5
Silicon electrical steels	M2(c); D2(d)	D2	...
Copper and aluminum alloys	A2; D2	A2; D2	A2(e)
Titanium and titanium alloys	D2(f); A2(g)	...	...

(a) L6 is also recommended for shearing carbon and alloy sheet containing >0.35% C. (b) D2 is also recommended for low-carbon and low-alloy sheet. (c) For sheet >0.8 mm (1/32 in.) thick. (d) For sheet >0.8 mm (1/32 in.) thick. (e) S5 is recommended for sheet >12.7 mm (1/2 in.) thick. (f) For sheet <3.2 mm (1/8 in.) thick. (g) For sheet >3.2 mm (1/8 in.) thick

of the work metal. In general, rotary shearing is used for sheet and plate less than 13 mm (1/2 in.) thick, and laser cutting is used for sheet and plate less than 25 mm (1 in.) thick; gas cutting is used for thicknesses of 13 mm (1/2 in.) or more.

Gas cutting is less suitable for cutting a single thickness of sheet or thin plate because the heat causes excessive distortion, but it is often feasible to minimize this problem by stack cutting (cutting several thicknesses at a time). Gas cutting is more versatile than rotary shearing; it can produce smaller circles than rotary shearing and can produce rings in one operation. Gas cutting, however, produces a relatively large heat-affected zone on the workpiece.

Laser cutting produces an extremely narrow kerf that provides unmatched precision for cutting small holes, narrow slots, and closely spaced patterns. Complex openings, contours, and patterns, which are impossible to cut with conventional tools, are routinely cut using a laser and require little if any additional processing. A smaller heat-affected zone than traditional thermal cutting processes minimizes distortion and improves part quality.

**Circle Generation.** For cutting circles, the workpiece is placed in a special fixture consisting of a C-shaped, deep-throated frame having a rotating pin or clamp point at its outer extremity. The maximum circle that can be sheared is governed by the depth of the clamp throat and by the amount of clearance necessary to permit the rotating workpiece to clear the deep part of the C-frame on the machine. Thus, when using square blanks, removal of the corners allows a larger circle to be cut.

There are two methods of holding the center point of the work metal during circular shearing. In one method, the work metal is clamped by a screw-type handwheel or by an air cylinder, each of which incorporates two pivoting pressure disks—one above and one below the workpiece. The disks permit the workpiece to rotate in a horizontal plane. The other method is by center pinning, in which a hole is drilled or punched in the work metal for locating and rotating it on a pin in the center clamping attachment. The hole is at the predetermined center of the circle to be produced.

Of the two methods, center pinning provides greater rigidity because the work metal cannot slip off center during shearing. The circle generated when the work metal is held by the clamping method may not be perfectly round if

the clamping fixture has not been properly located or if it has shifted because of pressure on the cutters. The disadvantage of center pinning is that a hole must be made in the work and must be closed by plug welding if it is not wanted in the finished product.

**Adjustment of Rotary Cutters.** The upper cutter head and drive of a rotary shear is raised and lowered by power; a clutch mechanism limits the upward and downward travel. Power movement of the upper cutter is essential (especially when cutting plate stock) because the shearing edges of the cutters must be moved toward each other in proper alignment in order to create the initial shearing action. In setting up, the work metal is often rotated in the clamp attachment, with the cutter exerting light pressure, to determine whether a true circle is being generated. Additional pressure is then applied by the vertical screwdown of the upper cutter to cause shearing.

Only the upper cutter is rotated by the power-drive mechanism. The pinching and rotating action of the upper cutter causes the work metal to rotate between the cutters, and the metal causes the bottom cutter to rotate. The position of the upper cutter in relation to the lower cutter is important. Figure 6(a) shows the setting for shearing a straight edge. Clearance between the cutters is as important as it is with straight knives. Overlap of the cutters, as shown in Fig. 6(b), produces a bevel cut. The degree of bevel up to a maximum of 30° can be adjusted by changing the amount of overlap of the cutters.

**Accuracy** of the sheared circle depends on the rigidity of the center clamping device, sharpness of the cutters, maintenance of optimal clearance between the cutters, thickness of the work metal, and cutting speed. For work metal up to approximately 3.2 mm (1/8 in.) thick, dimensional accuracy within  $\pm 0.8$  mm ( $\pm 1/32$  in.) can be obtained when generating a 760 mm (30 in.) diameter circle. With proper setup of equipment, the sheared edge will show only a slight indication of the initial penetration.

**Speeds** of 2.4 to 6.7 m/min (8 to 22 ft/min) are most commonly used for the rotary shearing of metal up to 6.4 mm (1/4 in.) thick. Speeds of 1.5 to 3 m/min (5 to 10 ft/min) are used for rotary shearing metal that is 6.4 to 25 mm (1/4 to 1 in.) thick.

**Flanging and Joggling.** With cutters replaced by forming tools, the rotary shear can be used to form flanges and joggles on flat stock. The

(a)

(b)

**Fig. 6** Two types of rotary shearing. (a) Conventional arrangement of cutters for producing a perpendicular edge. (b) Overlap of cutters for producing a beveled edge

**Fig. 7** Setup and tooling for forming a joggle in plate stock using a rotary shear

maximum joggle that can be produced is usually limited to the thickness of the work metal. Because the work metal is made to flow into a different shape during flanging or joggling, the amount of energy required reduces the capacity of the machine to 75% of the rated capacity for shearing. Figure 7 shows a typical setup for forming a joggle.

## Safety

Shearing machines must be equipped with devices for protecting personnel from the hazards of shear knives, flywheels, gears, and

other moving parts. The guards and safety devices used must be sufficiently rigid enough to withstand damage from operating personnel moving heavy material into position. The squaring shears used for sheet metal should have guards on all moving parts, including flywheels, hold-downs, and knives. The treadle, whether mechanical or electrical, should have a lock for supervisory control. Knife and hold-down guard openings should be large enough to provide visibility but small enough to keep the operator's fingers out of the danger area.

Proper opening dimensions are outlined in ANSI standard B11.4, "Safety Requirements for Shears."

The shears used for shearing plate are more difficult to safeguard because of the greater clearances needed under the hold-downs and upper knife to permit entry of the plate (especially when it is bowed or buckled). Guards on shears for plate should be of the type that raises only when the plate is inserted and then rests on the surface of the plate. When there is no workpiece in the machine, the guards

rest within 6.4 mm ( $\frac{1}{4}$  in.) of the surface of the table.

Shears should comply with the construction requirements of the Occupational Safety and Health Act and National Safety Standards. Additional safety information can be obtained from the loss prevention group of major insurance carriers for Workman's Compensation and the National Safety Council. Safety regulations also cover the maximum noise level permitted from a shearing operation to prevent permanent impairment of hearing.

# Flattening, Leveling, Slitting, and Shearing of Coiled Product

L. Chen, Technical Materials, Inc.

METAL PRODUCTION MILLS produce flat metal sheet and strip products into coil form, and the coiled product will be processed further for subsequent fabrication processes: flattening, leveling, slitting, and cut-to-length, normally called final coil processes. Flattening or leveling is used to correct shape in the coiled sheet, strip, or plate. Slitting divides a wide coil longitudinally into narrow coils for desirable width, while cut-to-length is to shear coiled plate, sheet, or strip transversely into flat pieces in specific length before further metal part or component forming.

## Flattening and Leveling

Flattening and leveling are processes used to correct shape defects in coiled sheet, strip, and plate to achieve a required flat-shape condition. They are widely applied in stamping, roll forming, cut-to-length, and slitting lines, in addition to their own separate coil process lines.

## Shape Defects

There are six major shape defects in coiled sheet, strip, or plate (Fig. 1): coil set; cross bow; camber; wavy edges; buckles within a sheet or strip such as center buckles or quarter buckles; and, finally, twist. Coil set and cross bow are attributed to a residual strained length difference between the top and the bottom surfaces. That is a minor difference in length from surface to surface that causes a curvature at the longitudinal direction (coil set) or at transverse direction (cross bow). Camber, wavy edges, and buckles are considered to be a result of a longitudinal length differential from edge to edge across the width. For example, the edges of the strip or sheet longer than the center will cause the wavy edges; vice versa, a center buckle will be generated when the center is longer. A combination of residual strained length difference in both surface-to-surface and edge-to-edge causes a twist in a strip.

**Buckles** are localized pockets or regions of excessive length or surface that must rise and fall

from the nominal plane of the strip in order to be accommodated by the surrounding metal. They look like a series of waves or domed areas and are sometimes called "oil-canning" in reference to the domed, snap-through bottom of metal oil cans. Buckles can occur anywhere across the rolled width and tend to repeat along the length. Buckles that occur in the central portion of the strip are referred to as *center buckles* (Fig. 2, 3) and those that are off-center are called *quarter buckles*. The term *full center* refers to a center buckle that has edge-to-edge coverage and extends for some distance along the length of the strip.

Center buckles, quarter buckles, and full centers can be created during cold rolling as a result of mechanical misalignment or of cross-sectional irregularities in supply coils.

**Wavy edges** consist of buckle-like distortions that exist whenever the edge is longer than other portions of the strip and usually occur at the immediate edge. Two examples of wavy edges are shown in Fig. 4 and 5.

**Herringbone** (Fig. 6) may occur during cold rolling and is recognized as a series of long, overlapping waves running at varying angles between the rolling direction and the transverse direction. A herringbone pattern generally covers the central portion of the metal width and results from application of insufficient tension for the cross-sectional area and strength level of the metal being rolled.

Fig. 1 Major types of shape defects in coiled flat product

Fig. 2 Center buckles in repetitive, elongated pattern. Similar, but usually rounder displacements, are called oil-can buckles. Source: Ref 1

**Transverse (cross) bow** is a curvature across the full width of the metal that renders it somewhat canoe-shaped, or gutterlike, along its length.

**Longitudinal corrugation** (Fig. 7) is a longitudinal condition similar to transverse bow except that the sense of the curvature changes sign at least once across the width of the metal. Corrugation is usually caused by application of excessive tension, to which foil is especially susceptible during continuous annealing.

**Curl** appears as a longitudinal curvature or sweep along the length of coiled metal (Fig. 8). Curl may be induced during rolling, or by passing the metal over a small-diameter roll, such that the combined tensile and bending stresses exceed the yield stress of the metal, leaving a degree of permanent curvature in the metal.

**Fig. 3** Center buckles in a random pattern. Source: Ref 1

**Fig. 6** Herringbone. Source: Ref 1

**Coil set**, similar in appearance to curl, is also a longitudinal curvature along the coil length. Coil set can occur when metal is wound onto a small-inside diameter (ID) arbor with excess tension. The smaller the ID, the thicker the metal, and the softer the temper, the greater is the likelihood of inducing coil set. Because the smallest ID exists at the core, this is where the greatest tendency for coil set exists. However, each succeeding wrap of coil is actually wound onto the diameter represented by the prior wrap, thereby reducing the bending stresses wrap-by-wrap and reducing the tendency for coil set wrap-by-wrap. Thus, coil set, within the coil where it is first formed, is highly likely to be most severe at the coil ID and decreases to a lower value or to zero at the coil OD. In practice, curl and coil set may not be easily distinguishable although resulting from different causes. Curl can have a higher degree of curvature than coil set. The curvature of the latter is normally no less than the radius of the coil as the material wraps.

**Twist** is a condition wherein a transverse axis held in the plane of the strip would rotate about the longitudinal axis when moved along the strip. Such a condition is evident in a short length of material if, when the material is freely placed on a flat surface, only three of the four corners touch the surface.

**Camber** is a side-wise curvature along the length of a strip. Although camber may be apparent in full-width material, it is often a problem in narrower material. It results from incoming strip shape defects, rolling residual stresses, excessive slit burr at one side edge of a slit strip, or excessive tension on one side edge of a slit strip exiting the slitter. The result, however, is always a strip with one edge longer than the other. In general, the narrower the width and the thicker the metal, the greater is the tendency for camber to develop.

Camber is a measure of curvature, which can be described as part of a circle with camber as a

**Fig. 4** Wavy edges in a regularly spaced pattern. Source: Ref 1

**Fig. 7** Longitudinal corrugation. Source: Ref 1

square function of the radial distance ( $L$ ) over which it is measured. Camber measured over different lengths can be expressed as:

$$C_2 = C_1 \left[ \frac{L_2}{L_1} \right]^2$$

where  $C_1$  is the camber measured over a length  $L_1$ , and  $C_2$  is the camber of the same strip piece measured over a different length of  $L_2$ .

## Flatteners and Levelers

Flatteners and levelers are widely applied in stamping, roll forming, cut-to-length and slitting lines, in addition to their own separate coil processing lines. Both flatteners and levelers are used for shape correction and control. However, their designs and thus effectiveness and scope of usage are different. It is also noted that the terminology used for different shape correction machines is not standardized. In this article, terms generally accepted in North America are used.

### Flatteners

The flattener, also called a straightener, for sheet, strip, and plate, incorporates a series of parallel upper and lower work rolls in a staggered position. The entry side and exit side of the upper frame housing the upper set of work rolls can be independently adjusted up and down. In some flatteners, the upper frame may also be adjustable for tilting within a small range along its longitudinal centerline. The work rolls can either have no backup rolls, as in a two-high flattener (Fig. 9), or be backed-up by a set of backup rolls, as in a four-high flattener (Fig. 10). The two-high flatteners typically have five to nine work rolls and their work-roll diameter is normally

**Fig. 5** Wavy edges in a random pattern. Source: Ref 1

**Fig. 8** Curl. Source: Ref 1

sufficiently large to avoid roll deflection. Two-high flatteners can be either a self-driven or a pull-through style. The four-high flattener allows the use of small-diameter work rolls because work-roll deflection is restrained by backup rolls. The four-high flatteners are typically self-driven and have seven to thirteen work rolls.

### Levelers

A **roller leveler** (or simply referred to as a leveler here) is similar to a four-high flattener in that the design involves four-high small-diameter work rolls. Unlike the four-high flattener, however, each work roll in the leveler is supported by a number of narrow backup rollers, instead of straight solid backup rolls (Fig. 11). This arrangement allows small work rolls and a close work roll spacing in the leveler for more capability in shape correction. A series of backup rollers at the same transverse position for all work rolls under the same frame are called a flight, and they have a common support housing extending from the entry to the exit of the roller leveler. Each flight of backup rollers can be vertically adjusted, independently from other flights, by either a mechanical or a hydraulic mechanism. A deflection of work rolls in the leveler therefore can be deliberately adjusted in a controlled manner. Roller levelers usually have seven to nineteen work rolls.

Some levelers have the five-high or six-high backup design for high surface finish quality strip. The six-high levelers have two additional rows of straight solid intermediate rolls between work rolls and adjustable backup rollers, each at the top and bottom frames. This arrangement prevents marking on the top and bottom surfaces of the strip but limits the capability to correct poor shape because the adjustable roller flights act on the intermediate rolls. The five-high leveler has only one row of the intermediate rolls between work rolls and backup roller, normally in the lower frame, while its upper frame contains only work rolls and backup rollers as in four-high levelers. Therefore, it gives better capability for shape correction than the six-high leveler, while preventing marking on one side of the strip surfaces. A roller leveler has a certain capability range in strip thickness for a given work roll diameter and roll spacing. Normally, the upper strip thickness limit is 3 to 4 times that of the lower limit.

Fig. 9 Two-high flattener with five work rolls

Roller levelers have the ability to control the deflection of work rolls so that one portion of the material across the strip width can be subjected to more bending than another portion. The bending causes a tension in the material of the outer layers in the strip and compression in the material of the inner layers near the work roll. At a certain bending radius, the stress in the material at the outermost layer will exceed the material yield strength and permanent plastic elongated deformation occurs. Similarly, the material at the innermost layer will experience compressive plastic deformation when the stress exceeds the material compressive yield strength. Higher-degree bending with a smaller bending radius causes more material to yield and makes plastic deformation shift inward to the neutral plane (Fig. 12).

*Multiple interchangeable roll cassettes* are used in a single roller leveler to extend its thickness capability range. Each cassette has its own specified roll diameter and roll spacing different from those in other cassettes.

*Cluster levelers* have a design with different diameter work rolls housed in clusters and provide a very wide range in strip thickness that the single cluster leveler is capable of leveling.

Fig. 10 Four-high flattener with backup rolls to support work rolls

Fig. 11 Four-high roller leveler with adjustable backup rolls

A **tension leveler** is a roller leveler with a mechanism for applying tension on the strip by bridle or pinch rolls. Simplified roller levelers without independent adjustments on each flight but with a tension mechanism are also called tension levelers by some manufacturers. During the tension leveling process, external tension is applied on the strip as it alternately passes over a series of very small-diameter work rolls, which are backed-up by bigger-diameter rolls. The strip is elongated under applied tension during the process. The range of the elongation in strip during tension leveling is typically from 0.1 to 5%.

### Principle of Shape Correction

The principle of shape correction by a flattener and a leveler is simple. In each case, a strip or sheet bends alternatively up and down as it passes between the upper and lower sets of work rolls. This causes selective plastic elongation in a portion of the strip or sheet. A local region of shorter length takes more external stress than a longer-length region in a strip, in addition to the fact that its residual stress is tensile. Therefore,

the short-length region will yield first and undergo more plastic elongation than the original longer-length region, where the residual stress is compressive and offsets a portion of the external stress. Then, nominal uniform strip length in different regions, surface-to surface or edge-to-edge, is achieved as a consequence of a series of reversed bending. The residual stresses in the strip are also reduced and redistributed in a more uniform pattern after a series of bends. During tension leveling, an external tensile stress applied on the strip makes the neutral plane shift toward the inner layer (Fig. 12). Higher tension results in tensile stress across the entire thickness of the strip and, finally, plastic tensile deformation across the entire thickness.

Figure 13 illustrates the principle on stress-strain curves in a simplified case, where curve A represents a short-length region material and curve B represents a longer-length region material. Initially, the difference in length between A and B is  $\delta_i$ , and the residual stresses are assumed to be zero. If a tensile stress from bending or an external tension exceeds the material yield strength, plastic deformation occurs, in addition to elastic deformation. When the stress is released after bending, both curves A and B will return along the slope of the elastic modulus. It can be seen that the difference in length between A and B at this point, represented by  $\delta_{f1}$ , is smaller than  $\delta_i$  (Fig. 13a). If the materials undergo a reversed bending at the next set of work rolls and there is no external tension, the stress on the materials becomes compression instead of tension; the stress-strain curves A and B will continue to the negative side—compression until the stress releases (Fig. 13b). If stress is

high enough to cause permanent (plastic) deformation, the difference in length between A and B,  $\delta_{f2}$ , at the zero stress becomes even smaller than  $\delta_{f1}$ . This process is repeated as multiple reversed bending continues when the material moves through a series of work rolls and, finally, the difference in length between A and B becomes near zero. It should be noticed that because of Bauschinger effect, the material yield strength in the regions A and B will not increase after plastic deformation during repeat reverse bending if no external tension is applied.

The outermost layer of a thin strip has less elongation than that in a thick strip at the same bending radius. To achieve the same amount of flattening or leveling results, a higher degree of bending (e.g., a smaller bending radius with a smaller bending wrapping angle) in a thin strip is required than the degree of bending required for a thick strip. This requires small-diameter work rolls as well as a shorter work roll spacing and a closer gap (e.g. more penetration) between upper and lower work rolls. However, small-diameter work rolls tend to bend under loading during processing. Therefore, backup rolls in four-high flatteners and backup rollers in levelers are used to control work roll deflection.

## Shape Corrections

**Shape Correction with Flatteners.** Both two-high and four-high flatteners can control and eliminate coil set and cross bow but cannot eliminate buckle and wavy edge. A flattener can reduce twist in a narrow strip, but eliminating

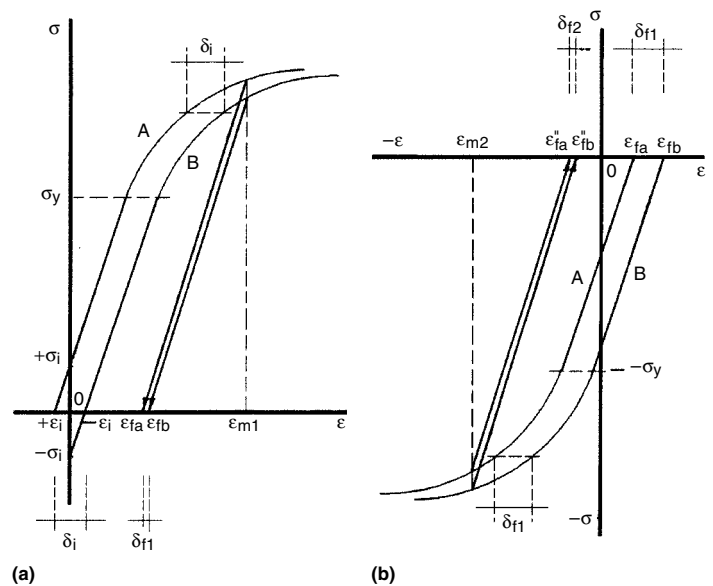

high-degree twist may also introduce another type of shape defect. Normally, flatteners cannot correct camber. However, a flattener with tilting adjustment ability along the longitudinal centerlines of its upper frame may reduce and eliminate a small degree of camber in a strip. A deliberate misalignment of a pull-through flattener to the line may be able to eliminate a camber in a narrow strip (<50 mm, or 2 in.). Auxiliary side push rolls near the entry side of a flattener are used for camber correction in a narrow strip (<100 mm, or 4 in. wide with thickness >0.6 mm, or 0.025 in.).

For a coil set strip, length difference between the top and bottom surfaces diminishes after a series of reversal bending in strip when it is passed between upper and lower rolls, and therefore, coil set is corrected to the flat shape in a properly set flattener. To correct cross bow, a much higher-degree bending is needed because the reduction in length difference between the top and the bottom surfaces in the transverse direction depends on lateral contraction resulting from longitudinal deformation. High-degree bending needs small-diameter work rolls for a small bending radius, and a closer work roll spacing for a small bending wrapping angle. This can be readily achieved in a four-high flattener.

The gap or penetration depth of work rolls at the entry side of a flattener should be tight enough for shape correction, and the initial gap setting at the exit side should be approximately equal to a strip thickness (Fig. 14). In most cases, especially with more than seven work rolls, the setting at the exit side will determine a final coil set direction (zero, down or up linear curvature)

**Fig. 12** Bending mechanism during flattening and leveling showing an effect on plastic deformation

**Fig. 13** Stress-strain curve illustration of reduction in a localized length difference by plastic deformation during flattening and leveling. (a) First imposed state of tension before it is released. (b) Continuing from the state of applied tension to a state of applied compression before the stress is released. Scale of strain is exaggerated for clarity.

Fig. 14 Setup of work roll gaps

when the entry gap is tight enough to remove the original coil set. Excessively tight gap of work rolls in a two-high flattener may cause overloading and thus deflection (bending) of work rolls. This may cause wavy edge in a wide sheet during flattening. The upper limit of flattener capability in material thickness and strength is normally restricted by unintended roll bending, while the lower limit (in material thickness) of flattener capability is determined by a work roll diameter and a work roll spacing.

**Shape Correction with Roller Levers.** Roller levelers can control and correct not only coil set and cross bow, but also wavy edges and buckles. This is because they have the ability to control the deflection of their work rolls so that one portion of the strip can be subjected to more deformation than another. In the case of the center buckle or longer center than the edges, the edges should be stretched more than the center until the same length is achieved between them. The backup rollers in the leveler should be set tighter on the edges than the center so that bending on the edges has a higher degree of bending than that in the center (Fig. 15). In contrast, if the strip has wavy or loose edges, the center should be stretched more until it has the same length as the edges. The roller levers should be set up closer in the center than on the edges (Fig. 16).

**Shape Correction with Tension Levelers.** Tension levelers can correct coil set, cross bow, buckle, and wavy edges, as well as twist and camber. As shown schematically in Fig. 17, a tension-leveler applies tension to the strip as it alternately passes over and under a series of very small-diameter, backed-up rolls. When used

Fig. 15 Roller setting in a leveler for correcting center buckle: tight for high degree bending at the edges

correctly, tension leveling has proved to be the most versatile tool commercially used for improving shape of coiled material (Fig. 18).

Tension leveling is the only effective method to correct camber. The set-up parameters of tension leveler include: diameter of work rolls, roll spacing in case an exchangeable roll cassette is used, adjustment at the entry side of each flight of backup rolls, adjustment at the exit side of each flight of backup roller, and tension or stretch elongation.

## Slitting

Slitting is a process to cut a single, wide strip, sheet or plate, normally in coil form, lengthwise into several narrower strips. During slitting, a moving strip passes between a number of circular blades or knives mounted on two parallel rotating arbors. Slitting can be applied to materials such as paper, plastics, composite, and fiber, as well as ferrous and nonferrous metals, from thin foil less than 0.01 mm (0.0004 in.) thick to over 25 mm (1 in.) thick plate. The discussions in this article focus mainly on metal coil slitting.

**Slitting Lines.** In simple terms, a slitting line consists of three essential units:

- An uncoiler, also known as a payoff or unwinder, for holding the coil and feeding the strip to the slitter
- A slitter with two parallel arbors holding the knives and other tooling for slitting the strip

- A recoiler, also called takeup or rewinder, for rewinding the slit strips (Fig. 19).

Other equipment can be added to the line for coil handling, strip feeding and guiding, shape correction, gaging, shearing, end joining, edge selvage disposal, packaging, and so forth.

The slitter itself consists of supporting structure and two parallel arbors, one above the other, mounted with shear slitter knives. The distance between two parallel slitter arbors is vertically adjustable to accommodate different diameter knives and different thicknesses of materials. This is normally done during slitter tooling setup or beginning of slitting. However, some computer numerical control precision slitters can perform a continuous minor adjustment according to the conditions of an incoming strip during slitting.

Slitting lines commonly have either one or two recoilers, although some are equipped with individual recoilers for each cut produced. On lines with only one recoiler, all cuts are wound on this recoiler and metal-separating disks or overarm separators are used to keep the individual cuts separated during winding. A disadvantage of single recoilers arises in slitting many cuts because the separator thickness must be accommodated between adjacent cuts, resulting in a fan-out pattern of the cuts from the tight-line slitter (Fig. 20). This situation may induce undesired camber and rippled edges in the slit metal. To avoid this problem, two recoilers are generally used such that each takes up every other cut across the width, thus eliminating fan-out, as shown in Fig. 21.

Modern slitting lines can slit a coil at a line speed of 300 to 400 m/min (980 to 1310 ft/min). Some modern slitter lines for thin strips are able to run up to 900 m/min (2950 ft/min). These slitting lines are normally designed for high productivity with fully automatic loading and feeding of an incoming coil and unloading of finish slit coils in very short time. Either exchangeable second slitter head or programmable automatic knife-position slitter head can be found in these slitter lines. The setup of slitter tooling on the second slitter head can be verified and adjusted by offline trial slitting. The exchange between the pre-setup second slitter head and the inline slitter head can be completed automatically within two or three minutes. The

slitting time of these slitting lines, therefore, can be readily above 65% of total operation time, which includes slitter set up time, incoming coil loading time, slitting time, and unloading time of slit coils.

Slitting lines are generally classified into three broad categories:

- Pull-through
- Driven
- Help-driven

The choice between pull-through and driven lines depends largely on strip shear strength and thickness, number of slit strips, slitting speed, and slit quality requirements. In general, when the metal strip to be slit is less than 0.25 mm (0.010 in.) thick, a drive or helper-drive slitter line is preferred because thin metal strip is likely to tear if it is pulled through a slitter head.

*Pull-through slitting lines* (Fig. 22) use a motor-driven recoiler to pull the strip through the slitter. The slitter arbors are not driven in this type of slitter. This type of slitting line is normally a tight line; that is, the strip is under tension from the uncoiler through the slitter to the recoiler. However, slack strands (Fig. 23) may

**Fig. 19** Three essential units of a slitting line to slit a wide coiled strip into narrower width coiled strips

occur due to differences in speeds of different strip sections.

*Driven slitters* (Fig. 24) have motors that drive the recoiler and arbors in the slitter. The payoff may also be driven. These motors are synchronized to maintain approximately constant speed of the metal as it travels through the slitting line. Driven slitters are preferred for thin strip because they allow winding of slit strips under lower unit tension. Driven slitter lines may operate with one or two slack strands between the slitter and recoiler, especially for thin metal strip, to allow for minor speed differences in different slit strips wound on a common winding arbor. The speed variation in the different slit sections is from variations in the slit-coil diameter due to poor shape and/or non-uniform thickness across the width of an incoming coil.

Looping is especially useful in slitting soft metal or thin-thickness material. Synchronization of the motors in a driven system can allow a reduction in the applied tension between two given points in the line. In driven systems, looping allows the metal to sag under its own weight, which allows it to find the path of least resistance. Three types of looping are illustrated in Fig. 25. In pre-looping, the loop is established between the coil payoff and the slitter, which reduces wrinkling and creasing of the metal as it enters the slitter. In post-looping, the loop is

established between the slitter and the rewinder, which minimizes distortion and damage to the edges of the slit widths as they scrape against the separators on the rewinder. This configuration is illustrated in Fig. 26.

Double-looping (Fig. 25), a combination of pre-looping and post-looping, offers the advantages of both to ensure minimal metal damage. A precision driven slitting line can be also a tight line or operated in the tight-line mode, especially when equipped with a tension leveler placed before or after the slitter and/or with a slip core recoiler.

*Help-driven-type slitters.* In the help-driven-type slitting line, the torque applied to the slitter arbors, from the slitter driven motor, reduces the tension on the pulled strip to avoid snagging at the entry slitter knives. The helper torque is insufficient to drive the slitters alone, thus avoiding the speed-match issue in a purely driven-type slitting line. The help-driven-type slitting line is in the tight-line configuration.

**Interactions between Knives and Strip during Slitting.** While dish knives are primarily used for slitting plastic film, paper, and metal foil, rotary slitter knives are most commonly used in metal strip slitting and are discussed here. The interactions between slitter knives and metal strip during slitting with proper slitter tooling and setup normally can be divided into the following four steps: (a) At the beginning of slitting,

**Fig. 20** Slitting line with one rewriter showing fan-out problem

**Fig. 21** Slitting line with two rewriters

when a metal strip moves forward to the slitter knives before a shearing point, plastic deformation occurs on the material by compressive force at knife contact surface. This can result in edge distortion or “rollover” along the slit strip edge, especially in soft materials. (b) As the metal strip moves further to the knife shearing point, the knives penetrate into the strip and create the flat, shiny or so-called shear or “burnished” surface on the portion of the slit edge. The depth of burnished shear surface portion depends on the material strength, ductility, and thickness of the strip as well as the slitter knife clearance. (c) As the knife penetrates further into the strip, the maximum shear strength of the material is exceeded, and fracture takes place, which results in a total separation of the material. The fracture surface on the edge appears dull, in contrast with the shiny, burnished shear area in the second slitting stage. The angle of fracture generally falls between 6 and 12° depending on the type and mechanical properties of the material. (d) Finally, a burr is formed on the strip edge on the opposite side of the rollover. Burr is attributed mainly to a compressive plastic deformation displacement around the edge corner of the knife. Figure 27 illustrates the exaggerated cross-section view of a single slit edge introduced by these four slitting stages.

**Slitter Tooling and Setup.** Slitters may be equipped with either standard (male/female) tooling or solid tooling setups. Solid setups may be used when tighter tolerances are required than those possible with standard setups. In the standard setup, slitter knives of a fixed or standard thickness (width) are used, and spacers are located between the knives to establish the desired slit width (Fig. 28). In this setup, the slit width is equal to the full spacer width of the female load, and the slit strip will have a burr pointing up. A standard slitter setup for three cuts is shown in Fig. 29, with alternating male and female loads on each arbor. These cuts, from left to right, will have edges with burr down, up, and down, respectively.

Figure 30 shows basic slitter tooling and one type (male/female) of slit setup in a single slit strip. The slitter tooling basically consists of knives, spacers, steel or rubber stripper rings over the spacers. It may also include metal or plastic shims of a thickness between 0.127 and 0.013 mm (0.005 and 0.0005 in.) for width match, but this practice is being replaced by shimless tooling in industry. The spacers and stripper rings in the male side can be simply substituted by a knife or knives, or whole male set of knives, spacers and stripper rings substituted by a single knife. Wood fingers, a type of

setup used in the past, may still be found in place of stripper rings in some slitters.

Appropriate slitter tooling setup is essential to obtain proper slit width, slit edge, and other slit qualities. The slit width is the distance between female knives as shown in Fig. 30. Knife horizontal clearance and vertical clearance (or overlap) are very important to slit quality, especially to edge condition. Too much horizontal clearance can cause excessive edge rollover and burr, while too tight horizontal clearance may cause bad edge as well as premature wearing or damage of slit knives. As a guideline, Table 1 lists the horizontal clearance and burnished percentage for different metals. When a strip thickness becomes thinner than 0.38 mm (0.015 in.), a horizontal clearance tends to be at the lower end of the listed percentage value or even lower, especially when edge quality is critical for burr-free. In most cases when metal strip thickness is below 0.127 mm (0.005 in.), a zero horizontal clearance is used with thin knives. Knife overlap is also called knife vertical clearance or positive vertical clearance. It depends not only on the thickness and strength of material strip to be slit, but also on other factors such as number of slit strips, horizontal clearance, knife sharpness, rubber ring diameter or steel ring pressure, and slitter arbor deflection.

Fig. 22 Pull-through slitting line. Source: Ref 1

Fig. 23 Pull-through slitting line with slack strands to accommodate minor differences in speed

Fig. 24 Driven slitting line

Fig. 25 Methods of looping in a slitting line. Source: Ref 1

A formula to decide knife overlap is difficult to give. Usually, for the same slitter, slitter tooling, slit material, slit width, and incoming width, the knife overlap increases with strip thickness from near zero for ultrathin foil to a maximum value for the strip at a thickness between 0.75 to 1.60 mm (0.030 to 0.063 in.), then decreases with strip thickness from a positive value to the negative side (as in Fig. 30). In practice, it is determined by operator experience using a trial and error approach. At the beginning of slitting, the arbors are adjusted to bring them together until all slit strips have clean cuts. Excessive knife overlap can cause excessive knife wear, coil set, camber, and wavy edges.

It is useful to use a stereoscope or common optical magnifier to check slit edge quality. Examination of shear/fracture ratio, appearance, and burr on slit edge and their consistency can determine whether the slitter tooling clearance setup is correct. Figure 31 illustrates a typical slit edge under stereoscope.

The selection of proper thickness knives, spacers, and their combination for required slit widths can be made using manual calculation or

readily by a commercial computer software program. For slitter tooling setup, Table 1 already gives the guideline for horizontal clearance. These are typical process parameters that can be applied universally with some math calculations, either by a computer program or manually. Other process parameters are specific for different slitter machines, different sets of slitter tooling, different materials, different materials thickness, and different width. A slitter may have hundreds of setup sheets, and different slitters with different sets of slitter tooling can have different process parameters for tooling setup even for the same material and same size.

**Slit Quality Attributes and Troubleshooting.** Quality attributes of slit strip

include: slit width, burr, edge quality, cross bow, and camber.

*Slit width* is the most important slitting attribute in slitting operations. A slit width tolerance of  $\pm 0.075$  mm ( $\pm 0.003$  in.) can be readily achieved for a slit width less than 75 mm (3 in.) and  $\pm 0.125$  mm ( $\pm 0.005$  in.) for a width less than 175 mm (7 in.) on a modern precision slitter. Slit width is equal to the distance between female knives if the strip is held flat at the slit knives. Verification of correct slitter tooling setup should be performed to check whether the width is within the required tolerance. A loose arbor nut can cause the slit width to become out of tolerance. Excessive arbor deflection, poor slitter arbor maintenance condition, or other slitter machine issues can be the reasons for poor width accuracy. Use of pressure boards or multiple deflection rolls at the entry side of the slitter knife can overcome an inconsistency in slit width due to poor shape of a thin strip.

*Burr* is normally found to some extent on slit edge. Dull slitter knife or too much horizontal clearance of the knives is a primary cause of excessive burr. Knife vertical clearance, machine rigidity, machine maintenance, and precision of knives also have effects on severity of burr. Checking the actual knife clearance by filler gages (measure/check the distance of a gap by inserting different thick metal "sheets" into the gap), inspecting knife sharpness, and readjustment of slitter tooling setting are among the first things to do for troubleshooting of excessive burr. Measure the distance of a gap by inserting different thickness of metal sheet into the gap. Plastic shim used in slitter tooling setup is not desirable because it may become soft and compressed and, thus, change the horizontal clearance when slitter tooling becomes hot during high-speed slitting. If burr-free edges are required, a subsequent device such as a deburr roll or file can be installed in the line to roll down the burr or to remove the burr.

*Poor edge quality* can be caused by too-tight slitter knife clearance when the edge appears rough or there are metal fines or slivers on the

**Fig. 26** Schematic of driven-type slitting line with single loop after the slitter. The uncoiler, slitter, and recoiler in the line are driven by separate motors synchronized to maintain constant speed of material being slit. Minor differences in speed may still require the use of slack loops in the pit.

**Fig. 28** Standard setup for one cut

**Fig. 27** Cross section view of a slit edge

**Fig. 29** Standard setup for three cuts

**Table 1** Guideline of horizontal clearance for slitter knife setup

Strip thickness >0.50 mm (0.0197 in.)

Materials	Ultimate tensile strength	Horizontal clearance	Shear/fracture ratio
	MPa (ksi)	% of thickness	
Annealed aluminum	103 (15)	5–7%	50/50
Annealed low-carbon steel, soft copper, medium alloy aluminum	207–276 (30–40)	8–12%	25/75
High-strength, low-alloy steel, alloy copper, annealed stainless steel, 70XX aluminum	414–621 (60–90)	15–18%	15/85
Cold-rolled stainless steel, high-carbon steel, beryllium copper, high alloy steel	690–1241 (100–180)	20–25%	<10/90

**Fig. 30** Detail view of slit edge with vertical clearance (overlap) and horizontal clearance

strip edge. Too-tight horizontal clearance causes double shear and break. Speed mismatch between the slitter and the recoiler in a tight slitter line can also result in poor edge. Inspection and adjustment of separators near or at the recoiler and knife vertical overlap are also recommended when poor slit edge is present.

**Turnover.** Another feature that may accompany a slit edge is called turnover, or pulldown. As shown in Fig. 32, turnover is a slight curvature along the slit edge created by the shearing action of the slitting process. Turnover, usually found only in very soft metal, is almost negli-

gible on the slit edges of precision sheet, strip, and foil.

**Cross bow** is a transverse curvature across the width in slit metal strip (Fig. 1). It can either come from an incoming material strip due to residual stress or poor shape or be introduced by poor slitter tooling setup. Normally, high cross bow has the same direction in adjacent slit strips if it comes from the incoming material. If the cross bow is introduced by poor slitter tooling setup, there is a need to check whether slitter knife horizontal clearance is too tight, slit knife overlap is too much, rubber ring diameter is too large, or steel ring pressure is too high.

**Camber** is width-wise curvature present longitudinally in the same plane of metal strip (Fig. 1). Camber can be introduced by the slitter or be attributed to an incoming material strip itself. To verify whether the camber comes from the incoming strip, one can simply flip over the incoming strip to observe whether the camber of the slit strip is in the same direction as the one before flipping. If the camber has the same direction from the slitter head, the camber is most likely introduced by the slitter tooling setup, and the slitter tooling then needs to be reset to correct the problem. Excessive burr on one edge of the slit strip also can cause camber when the slit strip is wound into a coil. The other slitter-introduced camber is due to the “fan-out” of slit strips from the slitter to the recoiler in a tight slitter line when there are many narrow slit strips. In this case, the slit strips near the edges may have more severe camber than the center slit strips. Troubleshooting of reverse direction camber along the same slit strip may require checking the slitter tooling and its setup, slitter arbors, housing bearings, and slitter design capability as well as an incoming material strip.

**Rewinding uniformity** describes how even the side edge of the wound finish slit coils is. The rewinding uniformity depends on strip shape condition, strip thickness uniformity across width, slit burr, residual stress in the material, and rewinding tension control during slitting. For an intermediate thickness between 0.40 and 1.5 mm (0.016 and 0.059 in.), separating plates between each slit cuts at the rewinder may be used to force the slit strip being wound to wobble only within a small range move during rewinding in order to achieve even rewinding uniformity for each slit coil. However, caution must be taken, otherwise a separating plate may damage the slit edge during rewinding.

**Edge Conditioning.** There are many applications that require reorientation or elimination of the edge burr on slit strip to facilitate handling, accommodate tooling clearances, or eliminate cracking during severe forming operations. In order to meet these requirements, the slit strip must be processed through specialized edge-conditioning equipment after slitting.

In cases where the intention is merely to reorient or mash down the burr to prevent personal injury or jamups in processing equipment, the edge-conditioning unit utilizes a pair or a series of rolls that flatten the burr, or turn it 90° from a vertical to a horizontal plane, as shown in Fig. 33(b). This method still leaves the strip with a burr, except that it sticks out instead of down, which is the direction of a slitting burr on an unconditioned edge (Fig. 33a).

A modification of this method is one in which the burr is turned 90° to a horizontal plane and then mashed along the edge of the strip, as shown in Fig. 33(c). Again, because the burr has not actually been removed, the strip cannot be thought of as deburred, although the resulting edge is satisfactory for some applications.

A truly deburred edge is one that has been processed through some type of cutting tool that actually removes the burr, resulting in a cross section such as that shown in Fig. 34.

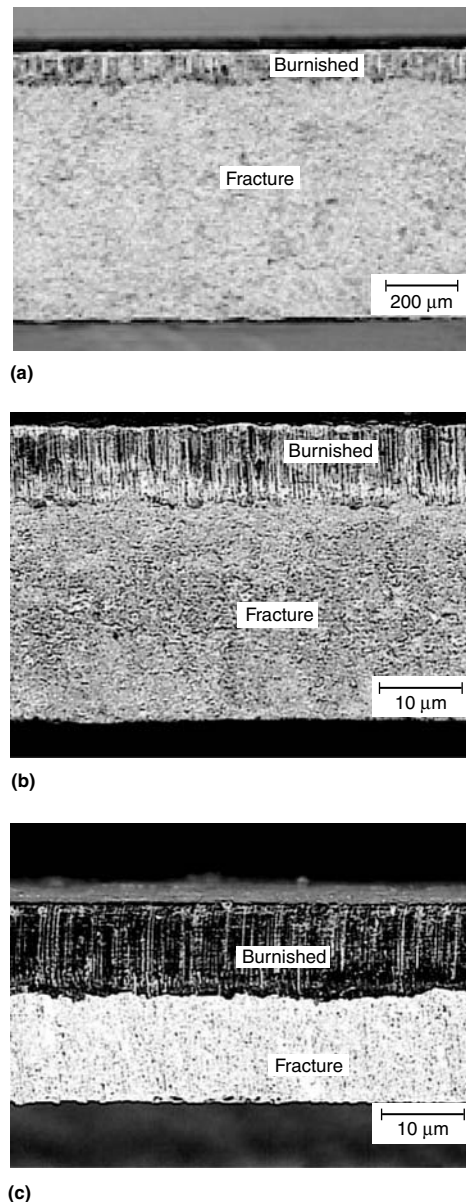

There are some high-performance applications that require edges from which have been removed not only the burr, but also the brittle metal in the fracture zone of the cut, to prevent the possibility of strip breakage emanating from edge cracks. This type of edge, generally called a rounded edge (Fig. 35), is produced by processing the strip through side-mounted shaving, filing, or grinding equipment.

## Cut-to-Length Lines

Cut-to-length lines are used to cut a metal plate, sheet, or strip transversely to a certain required length from coil. Various technologies, such as laser cutting, plasma cutting, and water jet cutting, can be used in cutting plate or sheet to a required length. However, cut-to-length lines are normally referred to the coil process lines using shearing or knife cutting. This section discusses only cut-to-length lines using straight knife shearing. Nevertheless, some fundamentals of line configurations in cut-to-length lines may be applicable when an alternative cutting method is used to replace knife shearing (see the section “Straight-Knife Shearing” in the article “Shearing of Sheet, Strip, and Plate” in this Volume for shearing principles, machines, operating parameters, sheared attributes, and other related topics).

All cut-to-length lines normally have at least four functions:

- The coiled product (sheet, plate, or strip) is first uncoiled and sent to a leveler or flattener.
- The metal is leveled or flattened by the leveler or flattener to ensure its flatness (see section

**Fig. 31** Typical appearance of slit edge showing shear penetration burnished zone and fracture zone. (a) Cold-rolled 304 stainless, ~10% burnished (sheared) vs. 90% fracture zone. (b) Annealed 304 stainless, 27% burnished (sheared) vs. 73% fracture zone. (c) Annealed pure silver ~50% burnished, 50% fracture

**Fig. 32** Turnover in slit strip

"Flattening and Leveling" in this article) before it is fed to a shear.

- The metal is then cut by the shear to a prescribed length.
- Finally, the sheared plates or sheets are stacked by a stacker.

The lines usually have feeding or conveyor systems to support these four functions. Some cut-to-length lines may also incorporate a slitter for edge trimming or strip slitting before the shear. In modern lines, the length-measuring or gaging system can be computer numerically controlled.

**Stationary Shear Lines.** There are two basic types of shear lines: stationary and flying shear types. Most cut-to-length lines employ stationary shears. The strip is stopped at the shear during the cut. These lines are generally more accurate than other types. There are three types of feeding arrangements for stationary shear lines: start/stop, hump table, and looping pit.

*Stop/start cut-to-length lines* (Fig. 36) are usually arranged so that the coil is fed into the shear to a prescribed length and then stopped during the cut. Upon completion of the cut, the

coil feed accelerates until it stops for the next cut. Close tolerances can be obtained, and line configuration is simple. However, the throughput (meter/min or sheet/min) is low. Therefore, these lines are generally confined to heavy-gage requirements. Stopping the coiled sheet in the flattener or leveler prior to shearing may leave a mark on lighter-gage materials.

*Hump Table.* Stationary shear lines with hump tables (Fig. 37) consist of an uncoiler, a flattener, and/or a leveler to correct for strip shape and to feed the strip over a hump table, a stationary shear, a gage table with retractable stop, and a stacker that stacks the sheared plates or sheets as they are delivered from the gage table.

The retractable stop with gage table, which follows the shear sequence, is used to control the length of the cut sheets. When the uncoiled strip touches the gage stop, it triggers a limit switch that actuates the shear to cut a sheet. Because the strip continues to flow from the uncoiler, it causes a hump to form above the hump table in front of the shear. When shearing is completed, the gage stop retracts, and the cut sheet is delivered to the stacker. As the cut sheet is removed, it activates a limit switch that resets the gage stop. Then, the shear opens, permitting the strip to slide forward through the shear and onto the gage table against the gage stop again, and the cycle is repeated.

*Looping Pit.* As shown in Fig. 38, many stationary shear lines have precision measuring feeder rolls just before the shear, instead of hump and gage tables. In these lines, there is a looping pit below the pass line just before the feed rolls and the shear. The flattener and/or leveler runs continuously. A slitter for edge trimming or

normal strip slitting can be added after the flattener or leveler and before the loop pit. The strip can be accumulated in the pit during a shearing cycle. Side guides control the feed angle of the strip for maximum cut squareness as it exits the looping pit and enters the shear. In some lines, the shear knives can be pivoted to cut trapezoidal blanks. The stacker is equipped at the end of the line to pick up and stack the sheared pieces for packing or subsequent operations. An air cushion may be used in some stackers for high surface finish quality cut-to-length products.

A stationary shear line generally provides the best squareness and length tolerance and most productivity for lighter-gage materials. Because of the nature of the loop, this feeding method is not practical for strip over about 6.4 mm (1/4 in.) thick. A hump line may be somewhat less expensive when the costs of installation are included to consider, but tolerance, squareness, and productivity may be sacrificed.

**Flying Shear Lines.** There are several different types of flying shear lines such as rocker (flying die), rotary drum, and oscillating. The lines are designed to shear metal strip or sheet in a way to synchronize a speed match with the moving metal. Because the shear action matches the speed of the moving strip, sheet, or plate, an accurate sheared length can be achieved without having to stop the strip and to restart each time of shearing. This continuous flow results in high line productivity. However, the flying lines normally cost more than stationary shear lines when a certain designed requirement in accuracy is needed. The lines may include an uncoiler, a flattener, measuring rolls, a flying shear, a runout conveyor, and a stacker. The rocker shear line is the least-expensive type in the flying shear lines;

**Fig. 33** Schematic of unconditioned and conditioned burrs. (a) Unconditioned edge with burr sticking down. (b) Conditioned edge with burr rolled 90° to stick out. (c) Conditioned edge with burr rolled 90° and then pressed along the edge

**Fig. 34** Edge with burr removed

**Fig. 35** Rounded edge after burr removal

**Fig. 36** Stop/start cut-to-length line. A strip travel is stopped to allow material to be cut to a prescribed length in the shear and then restarted until material is again at the prescribed length, when the stop/start cycle is repeated.

**Fig. 37** Stationary shear lines with a hump table. A strip continuously moves from uncoiler even during shearing sequence, causing the coil sheet to form a loop above the pass line and over the hump table. A limit switch actuates shear when the uncoiled strip touches a retractable stop.

**Fig. 38** Stationary shear lines with a looping pit. The loop pit is located below pass line and just before the feed rolls of the shear. A slitter may be added for edge trimming or strip slitting after a flattener or leveler.

it is best suited to light-gage sheet or strip shearing at slow speeds. The rotary drum shear is often used for light-gage narrow strip applications. It usually offers a high shearing accuracy at high speeds. The oscillating shear line is normally used for high-quality finished parts with higher speeds than rocker shear lines.

**Blanking lines** are a special type of shearing line. Blanking lines have the special capability of rapidly cutting and stacking relatively short and dimensionally accurate blanks as final parts.

**Cut-to-Length Line Capability.** The capability of cut-to-length line in maximum plate/strip thickness is limited by the shear capability but may also be affected by the thickness capability of a flattener or leveler in the line for tight requirements in flatness and dimensional accuracy. Dimensional accuracy of the cut sheet length depends on the line configuration, condition of the equipment, speed and length of sheet, and the condition of the master coil. Most modern lines generally can achieve accuracy to  $\pm 0.8$  mm ( $\pm 1/32$  in.), and up to  $\pm 0.4$  mm ( $\pm 1/64$  in.) when equipped with sophisticated devices.

# Selection of Materials for Shearing, Blanking, and Piercing Tools

SHEARING IS A PROCESS of cutting flat product with blades, rotary cutters, or with the aid of a blanking or punching die. Cropping of bars is a related process. The shearing process creates severe wear conditions, and this article describes some of the wear and material factors for tools used to shear flat product, principally sheet. The process is described in general terms, and the methods of wear control are briefly reviewed in terms of tool materials and lubrication. This is followed by sections on cold and hot shearing with tool steels. Most shear blades are solid, one-piece blades made of tool steel. However, carbide tooling is also used for long runs, and shear blades may be composite tools that consist of tool-material inserts in heat treated medium-carbon or low-alloy steel backings. Coatings also are instrumental in the economical improvement of tool life.

## Shearing Process

The process of shearing may involve cutting along a straight line with the aid of a shear blade, slitting with rotary cutters (Fig. 1), or cutting of contours with a blanking or punching die. Cutting straight lines with shear blades is discussed in more detail in the article "Shearing of Sheet, Strip, and Plate" in this Volume. General aspects are also described in the article "Principles of Shearing, Blanking, and Piercing" in this Volume.

**Fig. 1** Conventional arrangement of cutters in a rotary shearing machine, for production of a perpendicular edge

For this article, the basic process is illustrated by an example of hole punching (Fig. 2). When the tool first contacts the workpiece, elastic deformation occurs, the magnitude of which is a function of the elastic properties of the material, the cutting zone geometry, and the restraint provided by the adjacent material and die elements such as holddowns and strippers. Then plastic deformation (a slight extrusion) begins and, after some critical penetration, which is a function of the die clearance and the ductility of the material, cracks are generated at the die and punch edges (Fig. 2a). On further penetration the cracks propagate to complete the cut, while the cutting force reaches its maximum, which is only slightly dependent on clearance and not at all dependent on friction. The part must be pushed farther to remove it from the cutting zone; in this phase the force drops steeply and is partly attributable to friction on the die land and punch side surfaces. When cutting is done with a less-than-optimal clearance, secondary shearing takes place (Fig. 2b), resulting in a second peak in the force-displacement curve, the

magnitude of which is slightly affected by friction on the punch side surface.

The resulting cut surfaces are neither perpendicular nor very smooth—at best, peak-to-valley roughness ( $R_t$ ) of about 3 to 6  $\mu\text{m}$  transverse to the punch movement and 0.1 to 2  $\mu\text{m}$  parallel to it. Much-improved accuracy, perpendicular edges, and a smooth finish may be ensured by various special processes such as fine blanking (precision blanking), in which a specially shaped blankholder (Fig. 2c) imposes compressive stresses on the cutting zone, delays crack initiation, and ensures that the whole thickness is plastically sheared.

## Wear

Shearing creates severe wear conditions summarized as follows (Schey, Ref 1):

- Die and tool edges and the die land and punch side surfaces (the flanks) are exposed to the virgin surfaces generated in the course of

**Fig. 2** Schematic of the shearing process. (a) Side view of cut edge. (b) Torn edge with less than optimum clearance. (c) Blankholder for fine blanking

shearing. Relative sliding creates ideal conditions for adhesive wear of the edges and flanks (Fig. 3).

- The workpiece material suffers severe strain hardening. Even though the depth of this heavily deformed zone is shallow (typically, 30 to 50% of the sheet thickness), it increases local tool pressures and gives increased support to any abrasive particles that may be present, thus making them more damaging.
- Shearing forces and, particularly, localized pressures can be high. Forces can be reduced by selection of an adequate clearance (typically around 8%), but only slightly. High production rates involve impact conditions imposed at high rates of repetition. Repeated loading, especially in the presence of adhesive bonds, leads to spalling (fatigue) of the edges, which terminates the run. Crater wear is also possible on the punch end.
- Elastic deformation of the workpiece results in relative movement along the punch end face, first radially outward and then, after crack initiation, inward. This leads to abrasive wear on the punch face. By limiting elastic deflections, a stripper reduces this form of wear. In combination with high normal loads, crater wear is observed.
- Elastic springback of the workpiece material increases the pressure acting on the punch during retraction and thus increases flank wear, particularly in piercing of a hole.
- High production rates contribute to a temperature increase. In punching of stainless steel, the temperature rise was 80 °C (175 °F) under dry and 55 °C (130 °F) under lubricated conditions, values sufficient to increase adhesive and oxidative wear.
- Thermoelectric currents generated in shearing promote wear. This source of wear can be neutralized with a compensating circuit.

Fig. 3 Wear of shearing punch and die

**Wear patterns** include the following:

**Flank wear** can be characterized by length ( $l$  in Fig. 3) or area. Flank wear is important because it determines the length that is lost in regrinding. Its origin is in adhesion and abrasion and increases with the number of strokes—at a higher rate when the clearance is too small (Fig. 4). The wear length increases asymptotically to the maximum given by the punch penetration. A semiquantitative assessment is possible by inspecting the flank for scoring and pickup.

**Edge (tip) wear**, even though difficult to separate from flank wear (Fig. 3), is important in that it determines burr height. This, too, increases with the number of parts and is at a minimum at some fairly generous clearance (12% in Fig. 5). Excessive clearance (17% in Fig. 5) leads to a large burr also, but only because the part is finally separated by tensile fracture, and not because of wear.

**Face wear** is mostly abrasive in origin and as such increases linearly with the number of parts.

**Die life** is usually defined by the maximum tolerable burr height. However, wear cannot be judged from absolute burr height alone because this is a function also of materials properties. Burr height increases with increasing ductility and is thus generally less on cold-rolled than on annealed material. Similarly, alloying that reduces ductility also reduces burr height; on silicon steels burr height increased with decreasing silicon content and decreasing  $r$  value. Because of these effects, face wear may be considered as another indicator. Tool life generally follows a Weibull distribution—i.e., it has a normal distribution but with a finite lower limit. Excessive face wear causes plastic deformation in the form of dishing of the part due to contact prior to the initiation of fracture. The deformed blank shape can then be taken as a criterion for critical tool wear.

Fig. 4 Dependence of flank wear on punch-to-die clearance in cutting of steel blanks

## Wear Control

Friction does not affect the process of shearing (blanking, punching) itself, and therefore the prime purpose of lubrication is to reduce die wear. Adhesive, abrasive, fatigue, and chemical wear mechanisms contribute to a loss of punch and die profile and thus to an increase in clearance, with the consequent formation of a burr on the sheared part. Wear is reduced by appropriate choice of die materials and lubricants. Die materials must be hard and yet be of adequate ductility and also low adhesion. Die surface coatings play an important role. Lubricants are invariably compounded to minimize adhesive and abrasive wear through formation of boundary and extreme-pressure (EP) layers. However, because lubrication does not directly affect the shearing process, it is more meaningful to consider the various factors that influence wear control and die life.

General factors influencing tool life in cold-work applications are listed in Fig. 6. In general, selection of tool material and/or appropriate surface treatment should be based on the most likely failure mechanisms that may occur. Depending on the application (shearing, blanking, bending, drawing, etc.), cold working dies may experience wear, galling, indentation, chipping, and cracking damage characterized by:

- Abrasive or adhesive wear resulting in continuous or discontinuous material loss, respectively, which is related to sheet material, application, and process conditions.
- Galling due to physical and/or chemical adhesion of sheet material to the tool material. The severity of galling is dependent on surface smoothness, chemical composition of tool and sheet material and type, size, and distribution of hard phases in tool material.

Fig. 5 Effect of clearance on burr development in blanking of steel sheet

Surface coating may reduce or eliminate galling.

- Plastic deformation if the working stresses are higher than the compressive yield strength of the tool material.
- Chipping due to the stresses from the process and the fatigue resistance of the tool material.
- Cracking due to the stresses in the process, the length, and the geometrical configuration of an existing crack result in a stress intensity higher than the fracture toughness of the material.

These factors depend on the cold-work application. In blanking, all of the failure mechanisms may appear, whereas in press forming applications, galling, adhesive wear, and plastic deformation are the normal failure mechanisms encountered. Damages caused by plastic deformation, chipping, and cracking are often not controllable and should be avoided to prevent costly production interruptions. Wear and galling are more predictable failure mechanisms and can be controlled by a scheduled maintenance of the die sets.

**Tool Materials.** Because of the prominence of adhesive and abrasive wear, both tool material composition and hardness are important die-life factors. However, excessive hardness increases spalling. The danger of spalling, chipping, and cracking demands some measure of ductility and toughness. Wear resistance also depends on the hardness of the carbide phase ( $H_c$ ) that is dispersed over an effective area fraction of the surface ( $\alpha$ ) dispersed. Wear resistance of tool steels thus may not be simply a matter of hardness of just the tool-steel matrix ( $H_m$ ) but rather an effective hardness ( $H_e$ ) such that:  $H_e = H_c + (1 - \alpha) H_m$ .

Commonly used tool steels for sheet-metal fabrication include 5 wt%-Cr tool steel (AISI

A2) and 12 wt%-Cr tool steel (AISI D2). However, these materials (cast or wrought form) may not be the most effective choice in more demanding forming or cutting applications with higher-strength sheet materials or thicker high-strength materials. Ductility and toughness of A2 and D5 tool steel may also limit die life, especially in cutting applications that put higher demands on wear resistance, strength, and ductility as compared with forming operations (see the article "Selection of Materials for Press-Forming Dies" in this Volume for general information on press-work tool materials).

Wear resistance of tools for shearing, blanking, and piercing is achieved with dispersed quantities of hard particulates, typically carbides, in various types of materials, including:

- Cemented carbides (tungsten carbides in a cobalt matrix)
- Steel-bonded carbides (titanium carbides in a steel matrix)
- Powder metallurgy tool steels

Carbide tooling is commonly for long runs. Steel-bonded carbides have an intermediate level of wear resistance between tool steels and cemented carbides based on WC-Co. They consist of 25 to 45 vol% TiC homogeneously dispersed in a steel matrix. Matrices include tool steels, maraging steels, and martensitic stainless steels. Steel-bonded TiCs respond to heat treatment and are machinable by conventional methods when the binder is in the annealed condition. Fully hardened steel-bonded carbides can be tempered at varying temperatures, thereby obtaining greater toughness than WC-Co. However, this gain in toughness is accompanied by some sacrifice in hardness. Steel-bonded carbides are not recommended for cutting tools in machining because the hardness drops off

rapidly at the high temperatures developed during machining. They are, however, used for blades, knives, and stamping dies in cold-working applications (see the article "Selection of Materials for Press-Forming Dies" for more information on steel-bonded carbides).

Powder metallurgy (P/M) tool steels are used in cold-work operations where a combination of good wear resistance and compressive strength (high hardness) is required. Powder metallurgy methods allow production of tool steels with vanadium carbides for wear resistance. Vanadium P/M tool steels are used for punches and dies in cold-forming and stamping operations, and they are considered a cost-effective replacement for tungsten carbide and steel-bonded carbide tools, particularly where these materials are prone to chipping and breakage or where the cost of these materials is prohibitive. Vanadium P/M tool steels are particularly well suited for cold-working applications because of their excellent combination of wear resistance, toughness, and grinding characteristics over a wide range of hardnesses.

The first P/M tool steel with high vanadium for high-performance wear applications was Crucible CPM 10V (or PM 10V) (Crucible Materials Corp., Syracuse, NY), which was introduced commercially in 1978. Also developed at about the same time were modified grades with a lower-matrix carbon and slightly lower vanadium content for better toughness. More recent P/M tool steel development work has focused on the following:

- Compositions containing 15 to 18% V with up to 30% by volume of primary metal carbide-(MC)-type carbides for even more wear resistance
- Low-to-intermediate carbide volume fraction materials moderately alloyed with vanadium and chromium to optimize the toughness properties while still maintaining good wear resistance
- High-vanadium, high-chromium compositions for wear applications that also require good corrosion resistance

More information on P/M tool steels is contained in the article "Selection of Materials for Press-Forming Dies" in this Volume. These high-performance P/M tool steels are used for a wide range of cold-work punch-and-die applications such as long-run stamping, fineblanking, shearing, and piercing. For example, Fig. 7 shows a typical high-production-rate, progressive stamping die application in which CPM 10V punches were compared with D2 steel and an M4 P/M tool steel (Crucible CPM Rex M4). The material being stamped was a 0.381 mm (0.015 in.)-thick copper-beryllium strip. In one operation, D2 piercing punches at 60 to 62 HRC averaged 75,000 parts before losing size; CPM Rex M4 at 64 HRC showed some signs of wear after 200,000 parts. The CPM 10V punch showed no wear after 400,000 parts and ultimately produced over 1.5 million parts. Other

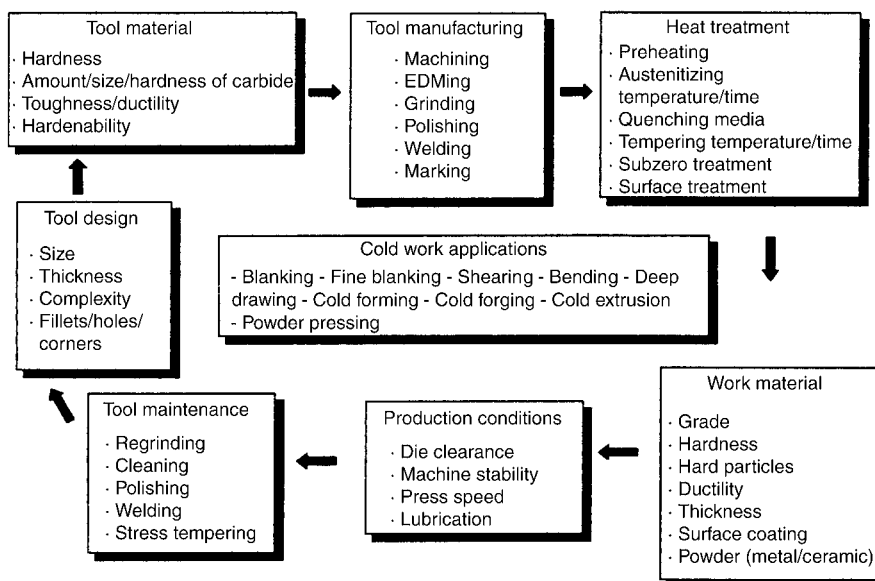

Fig. 6 Factors influencing tool life in cold work applications. Source: Ref 2

parts produced by punching and blanking with P/M tool steels are shown Fig. 8 and 9.

**Coatings and surface treatments** to improve tool performance include nitriding, hard facing with nickel-base alloys, boronizing, vapor deposition coating, and, hard-chromium coating. At least a doubling and as much as a quadrupling of tool life can be expected. Chemical vapor deposition (CVD) coatings with TiC is well known. The benefits increase with increasing sheet thickness, and up to a hundredfold increase in die life is found. Tools coated with TiC also greatly improve the surface roughness of fine-blanked parts. Physical vapor deposition (PVD) of hard coatings is also useful with better dimensional control, lower treatment temperature, but with less resistance to abrasive wear than CVD coatings (Fig. 10).

Since the first introduction of hard coatings, many types of single and multiple CVD and PVD coatings have been developed. The first real large-scale application was CVD coatings of TiC for cutting tools and, later, forming tools. Deposition of thick, hard coatings by PVD methods was initially more difficult, but now PVD methods permit coatings with thicknesses exceeding 10  $\mu\text{m}$ . This allows the benefits of PVD for applications that used to require CVD. Physical vapor deposition techniques can eliminate the need for an additional heat treatment and risk for change in dimensions can be eliminated. In addition to wear protection, modern PVD coatings can also enable dry or nearly dry metal forming due to very advantageous low friction properties. The inherent low friction of many carbon-base coatings not only gives a low friction, but it also prevents cold welding (galling) of work material on the tool. Current industrial trends to reduce the consumption of lubricants in forming operations, are expected

to further increase the application of these coatings.

**CVD** (Ref 2). The CVD method for tool coatings commonly include TiC, TiN, and TiCN. Process temperatures for adequate growth rate are about 1000 °C (1830 °F). This temperature is far above the tempering temperature of tool steels, and so a post heat treatment is necessary.

**Fig. 8** Parts with holes punched by P/M tool steels. Parts include: punching of fine slots in brass parts for clocks; punching of 3 mm (0.118 in.) holes in high-carbon steel (0.7% C) sheet (240 HB); punching of holes in chain links made of 0.55% carbon steel with a thickness of 2 mm (0.079 in.) and a hardness of 290 HB. Courtesy of Uddeholm Corp.

This has to be performed in a reducing atmosphere, or vacuum, because the Ti-based coatings oxidize above ~550 °C (~1020 °F). The post treatment establishes some limitations on which parts can be coated with CVD. These are mainly related to demands involving very high tolerances and/or when long and slim objects are to be treated. There is no real limitation for CVD and coatings into cavities and holes (compared with PVD) because it is only a gas distribution related limitation. Normal coating thickness with CVD is in the range of 4 to 10  $\mu\text{m}$  with process time typically between 5 and 8 hours.

**PVD** (Ref 2). Tool coatings by the PVD method include TiN, TiAlN, and CrN. Titanium

nitride is the classic and most universally used coating and is relatively easy to apply as compared with other coating materials. Physical vapor deposition TiCN coatings were found to offer better wear resistance than TiN. The relatively high hardness, high compressive stress, and the fact that TiCN often has a gradient as well as a layered structure enhances the wear resistance of the coating. Titanium aluminum nitride has been found to form a thin layer of alumina ( $\text{Al}_2\text{O}_3$ ) on the surface. This prevents degradation at high temperatures, which is why TiAlN outperforms TiN as well as TiCN in applications where the contact temperature is relatively high.

The most favorable properties of CrN are its very high toughness, in combination with a relatively high hardness (2000 HV) and a low adhesion to some engineering materials, e.g., Cu. The latter property has been utilized in metal forming of copper with very good results. CrN has also showed good results as a wear-resistant coating in corrosive environments. Physical vapor deposition coatings display unique properties compared with the corresponding bulk materials (if these even are possible to make). Extremely high hardness (ranging from 2000 for CrN to 3500 HV for TiAlN), high toughness, excellent wear resistance, and chemical inertness are typical examples. These are due mostly to the fact that PVD processes tend to yield fine-grained coatings, with fairly high residual (compressive) stresses.

A group of PVD coatings that frequently are used in applications where wear resistance in combination with low friction is required are diamond-like carbide coatings (DLC). These coatings typically are doped with metals, e.g., Cr or metal carbides such as WC. Typical applications are ball bearings and other wear parts where low friction is required. The beneficial low friction property of DLC coatings makes them increasingly interesting also for different tooling applications in which low friction is an important property. Dry metal forming, deep hole drilling, dry machining in soft materials such as aluminum and so forth are examples of applications in which DLC coatings already have proved to be a successful choice.

Carbon coatings containing metal (WC/C) and the combination of hard coatings (TiN, TiCN, TiAlN) with WC/C reduce the erosion tendency, and in some cases, they even permit a lubricant-free manufacturing process. Ductile materials such as aluminum, austenitic steel, or galvanized materials with carbon coatings can be correctly processed.

**Workpiece Materials (Ref 1).** The workpiece material is of importance from the points of view of both adhesive and abrasive wear. The presence of abrasive oxides or coatings is, obviously, damaging. Thus, a softer bainitic steel covered with a thicker oxide film suffers greater wear than a harder strip covered with a thinner blue oxide film, whereas a polished (bright) strip minimizes abrasive wear. Similarly, the  $\text{SiO}_2$  powder found in some insulating coatings

on transformer steel contributes to increased wear.

The absence of an oxide is, however, not always desirable. When adhesion is a problem, some oxide is preferable. Adhesion becomes more important with smaller clearances, and below 5% clearance the harder strip suffered greater wear because its thin oxide could not prevent adhesion. Chipping then becomes a danger. Adhesion is governed by the tool/workpiece materials combination. With an austenitic stainless steel, TiC reduced wear substantially but suffered from spalling. In contrast, a TiN coating virtually eliminated wear (Fig. 11). However, with a ferritic stainless steel it was TiC that eliminated wear while TiN only reduced it.

**Lubrication.** Various lubricants are effective in reducing wear, especially wear that is due primarily to adhesion. Liquid lubricants form a squeeze film when the punch hits the sheet. Most of the film squeezes out, but in doing so it also lubricates the end face and reduces face wear. The squeezed-out oil is available to seep into the cutting zone, reducing adhesion on the punch flank. As the punch retracts, the oil lubricates the flank, reduces the retracting force, and minimizes scoring and adhesive wear, but also causes the part to stick to the punch face.

Because of the need to reduce adhesion, most lubricants are compounded. Repeated contact and elevated temperatures activate EP additives, and these are found in all formulations except those destined to be used with aluminum alloys. Heavier sheet imposes more onerous duties, and therefore both base oil viscosity and additive levels are higher. Aqueous lubricants can be used, although oil-base ones are more suitable for severe duties. Liquid lubricants are helpful also in removing wear debris, which becomes a major cause of wear especially when clearances are large, and thus adhesive wear is less severe.

Of the most frequently used sheet metals, austenitic stainless steel is prone to adhesion and requires a minimum of 7.5% Cl in the oil.

Fig. 11 Effect of punch surface treatments on wear measured in a simulation test

Ferritic stainless steel is next in severity. Carbon steel, especially in thicker gages and at higher hardness levels, creates severe conditions, and both chlorine and sulfur are effective.  $\text{MoS}_2$  and/or polytetrafluoroethylene (PTFE) powder also can be effective as additives. Very low-carbon steel, with its tendency to smear, necessitates frequent regrinding of carbide tooling; the use of a lubricant with active sulfur dramatically increases die life. Oils with boundary additives are usual for aluminum alloys, while both boundary and EP additives are often employed for copper alloys. If the part is cleaned soon after forming, sulfur compounds are allowable. Various other substances, such as caprolactam-base lubricants, have been reported.

Coatings can be effective too. In blanking of austenitic stainless steel, a PVC coating has been used. Similarly, some of the insulating coatings deposited on transformer steel, such as an isophthalic-acid-base alkyl film or a fused Mg-phosphate-chromate-borate coating, reduce wear. Inorganic coatings, especially those containing silica, increase wear and spalling.

Lubricants are effective also in fine blanking, especially in reducing flank wear. Transverse roughness of the part improves with chlorine and sulfur additives and with higher oil viscosity. By appropriate shaping of the die elements, lubricant reservoirs can be formed (Fig. 12) and the quality of cut improved.

Thick plate is sometimes punched hot. Hot forging lubricants are generally suitable, ranging from graphitic formulations to glass cloth.

## Shear-Blade Tool Steels

Most shear blades are solid, one-piece blades made of tool steel. However, some are composite tools that consist of tool-material inserts in heat treated medium-carbon or low-alloy steel backings.

**Cold Shearing and Slitting of Metals.** Tool steels recommended for cold shearing of various metals are presented in Table 1, and blade materials for rotary slitting are given in Table 2. The composition and thickness of the material being sheared are the most important factors in the selection of a blade material. Other significant factors are cost, availability, heat treating characteristics, and previous experience in similar applications.

Fig. 12 Lubricant pockets developed in fine blanking by use of appropriately shaped tools

Tool steels vary in toughness and wear resistance, and the metals being sheared vary in hardness and resistance to shearing. If the material to be sheared is very thin and of relatively low hardness, the shear-blade material can be low in toughness but must have optimum wear resistance. For shearing material of greater thickness and higher hardness, it may be necessary to decrease blade hardness, or change to a less wear-resistant blade material or to a shock-resistant tool steel having a hard case over a tough core, to obtain the toughness needed to resist edge chipping. For example, D2 tool steel is recommended for shearing any metal substantially less than 6 mm ( $1/4$  in.) thick, but for thicknesses of 6 mm and greater, tool steels of greater toughness must be used (successively, A2; A9; and the shock-resisting types S2, S5, and S6).

**Effect of Hardness on Wear.** The rate at which a blade wears in cold shearing depends chiefly

on its carbon content and hardness. As shown in Fig. 13(a) and (b), shallow-hardening steels such as W2 may equal D2 in performance until several sharpenings have ground the hardened stock away; then hardness is lower, and life between grinds decreases accordingly. In these tests, shallow-hardening W2 was superior to deeper-hardening S2 until about 1.5 mm (0.060 in.) had been removed, because of the higher initial surface hardness of W2.

Use of a low-hardness blade for cold shearing will result in short blade life. A blade made of S4 or S5 tool steel with a hardness of 44 HRC wore three times as fast as one with a hardness of 54 HRC when other conditions were equal. A similar comparison of blade wear as a function of hardness for S4 and D2 blades is given in Fig. 13(c).

Recommendations on hardness of blades for cold shearing cannot always be made without knowledge of operational details. For

example, a D2 blade performed satisfactorily at 61 HRC in one application, but blades at this hardness broke under similar operating conditions in a different plant. Blades made of D2 tool steel at 58 to 60 HRC usually perform satisfactorily in shearing mild steel up to 6 mm ( $1/4$  in.) thick, and in many instances, D2 shear blades have been used successfully at 60 to 62 HRC. However, in shearing metals such as high-strength low-alloy steels, hardness of D2 blades must be kept below 58 HRC to prevent breakage.

The shock-resisting group S tool steels are used at hardness levels from 50 to 58 HRC. Blades with hardnesses near the higher end of this range are recommended for shearing steels 6 to 13 mm ( $1/4$  to  $1/2$  in.) thick and for nonferrous metals. For shearing harder or thicker metals, blades with hardnesses nearer the low end of this range are used in order to compensate for increased shock loading. Table 3 gives some typical hardnesses of blades used in ten different plants for cold shearing of specific ferrous and nonferrous products.

#### Tool Steels for Hot Shearing of Metals.

Shearing is done at elevated temperatures when the work material is thick and resistant to shearing or when hot shearing is otherwise desirable as part of the manufacturing process. The strong secondary hardening of group H tool steels provides sufficient resistance to softening to make them useful for shear blades operating at temperatures up to 425 °C (800 °F).

Type H11 tool steel is satisfactory for most hot shearing operations. The slightly more expensive types H12 and H13 also have been recommended. No data are available that prove any of these three steels to be superior to the other two. More costly steels such as H21 and H25 are recommended only when H11 has been tried and found to be inadequate. In many instances, however, higher-alloy tool steels are used for shear blades. For example, one large mill used H25 as the standard blade material for hot shearing aluminum at 150 to 425 °C (300 to 800 °F), as indicated in Table 3.

Hardness of blades for hot shearing varies considerably with conditions such as thickness and temperature of the metal being sheared, and type and condition of available equipment. However, hardness is usually kept within the range from 38 to 48 HRC. In one steel mill, H12 tool steel at 45 to 47 HRC is used for slab shear blades 1.45 m (57 in.) long, 125 mm (5 in.) high, 75.4 mm (2.969 in.) thick at the top and 73.0 mm (2.875 in.) thick at the bottom. In another mill, slabs and blooms are sheared with blades made from a steel containing 0.35 C, 0.90 Mn, 1.00 Cr, 1.25 Mo, and 0.25 V, hardened to 38 to 42 HRC.

The temperature of the metal being sheared influences blade life. Higher-alloy blades may be required if the metal being sheared has high strength at elevated temperatures.

Hard-faced blades are satisfactory, and in some plants are used exclusively, for hot

**Table 1 Recommended blade materials for cold shearing flat metals**

Material to be sheared	Blade material(s) for work-metal thickness of:		
	6 mm ( $1/4$ in.) or less	6 to 13 mm ( $1/4$ to $1/2$ in.)	13 mm ( $1/2$ in.) and over

shearing. Table 4 summarizes data on blade life in one steel plant where hard-faced blades are used for most hot shearing operations.

**Shear-Blade Life.** Service data on life of shear blades are scarce because maintenance programs employed in most high-production mills call for removal and redressing of blades, regardless of condition, during scheduled shut-downs. Available data report blade life in terms of number of cuts, linear footage (in slitting), tonnage, or time between redressings. The service data in Table 3 encompass all of these variables.

The number of cuts per edge before regrinding is the most common basis of evaluation. For different types of shearing, the number of cuts reported has varied from 5000 to more than 2 million. Therefore, meaningful comparisons

can be made only when conditions are nearly identical. Even when identical blades are used for the same shearing operation, life may vary by as much as 100%. This is substantiated in Fig. 14, which presents data on performance of 33 blades with carbide inserts used for shearing small rods. Wide variation in blade life also is characteristic of hot and cold shearing of nonferrous metals (see Fig. 15).

### Materials for Machine Knives

Unlike materials for metal-slitting applications, materials for knives used in cutting papers, films, and foils usually are selected on the basis of cost and wear resistance, without considera-

Fig. 14 Statistical distribution of life for shear blades with tungsten carbide inserts. Variation in life of 33 identical shear blades used for the same operation. Blades were made of carbon steel with cemented tungsten carbide inserts (15 to 30% Co) for the cutting edges. Material sheared was 4620 steel rod, 8.7 mm (0.343 in.) in diam, at 149 to 187 HB.

Fig. 15 Variation in life of identical blades used for shearing nonferrous metals

tion of toughness. This allows wider latitude in selection of tool materials, which often results in better performance with fewer compromises. The final choice must be influenced by specific production requirements, maintenance considerations, and the projected life of the tool being used.

Selection of tool materials for shearing and slitting papers, films, foils, and textiles is complicated by the vast array of materials to be cut and by the equally numerous types of tools and methods employed for such operations.

It is common to use the term *machine knives* to identify those tools that are most commonly used to slit, score, shear, trim, perforate, or otherwise cut very thin stock. There are two main categories of machine knives:

- Circular knives, which include score cutters, shear cutters, burst cutters, and single knife cutters (such as slicers and disc knives)
- Straight knife cutters such as trimmer knives, guillotine knives, sheeter knives, cutoff knives, and specialty knives.

Materials for these various knives are described next.

### Circular Cutters

Circular-knife design includes coating or impregnation of low-alloy or carbon steels with wear-resistant materials and use of laminated steels produced by cladding low-cost cores on one or both sides, depending on bevel configuration, with high-alloy, wear-resistant alloys such as group D and group M tool steels. Knives tipped with cemented carbides have become popular for certain types of service, especially in shear slitting of coated films. The advantages of extremely long life frequently outweigh the expense and difficulties encountered in proper setup and maintenance of such tools.

**Score Cutters** are circular knives that exert pressure on the material to be slit by crushing it against a surface (usually a roll or sleeve on a shaft) that is harder than the cutter. Such knives usually have a double bevel at the cutting edge.

Score cutters are most commonly made of 52100 steel because this material is widely available in bar form and is well suited to mass production and easy maintenance by the user. Score cutters are hardened to 60 to 62 HRC, a hardness level that is adequate for most operations and that will not result in scoring of an opposing platen sleeve or hardened roll. Such sleeves and rolls are made of 52100 or carburized steel, hardened to not less than 60 HRC. Alternative materials for score cutters are O7 and D2 tool steels, both of which are available as bar stock. These steels are heat treated to 60 HRC or higher, the same hardness as that specified for 52100 steel cutters.

Score cutters generally should be made of bar stock, not of sheet. The more uniform directional properties of bar stock yield more

consistent service life. The angle and radius of the double bevel are important determinants of performance, as is the pressure with which the knife cuts against the platen sleeve. Group M and group T high-speed steels are not recommended: score cutting cannot make full use of their high hardness and resistance to softening at elevated temperatures, and their higher cost is not justified. In addition, brittle, high-hardness tool materials should not be used for score cutters because they will give unsatisfactory service.

Finally, because most score cutters are dry ground by the user, materials must be selected from only those steels that will retain their hardness under these conditions. A properly adjusted score cutter will slice about 350 km (1 million feet) of paper between sharpenings.

**Shear Cutters** are circular knives that utilize the scissor-cutting principle, comprise pairs of opposing knives through which the material to be slit is passed.

Shear cutters can be produced from a much wider array of alloys, the choice being influenced by such factors as tool design, material to be cut, machine design, and maintenance limitations. The entire range of tool steels (including the popular 52100 and other low-alloy types plus the higher-alloy group D, group M, and group T steels), as well as specialty tool steels and cemented carbides, can be considered. For standard applications, 52100 and O1 are selected most often, chiefly because they are readily available as sheet, bar stock, or tubing. Most types of paper can be cut efficiently and economically with these tool steels. Cutting of coated and impregnated papers sometimes results in premature wear of low-alloy tool steel cutters, in which case D2 is a suitable alternative. Films and foils—whether plain, laminated, coated, or metallized—usually can be cut more efficiently with knives made from tool steels of higher alloy content, such as group D or group M tool steels, or specialty tool steels such as CPM 10V, hardened to 62 to 64 HRC.

In many instances, other considerations also have strong influences on selection of materials for cutting tools and on tool performance, including the design of the knife or machine, the surface finish of the tool, and other limitations imposed by maintenance or production practices. High-alloy tools are necessarily more sensitive to misuse and require greater skills in setup, operation, and maintenance.

Certain films, such as polyester coated with iron oxide or chromium dioxide (magnetic tape), are particularly destructive to knife blades. For these applications, expense becomes secondary to performance, and group M and group T high-speed steels (including the cobalt-containing types M42 and T15) are used to obtain maximum hardness and wear resistance. High-speed steels are preferred because they seem better able to preserve the high degrees of accuracy and surface finish required for such knives. CPM 10V also is well suited for these applications, offering a higher degree of wear resistance than most of the alternative materials.

**Burst cutters** either penetrate the material with a progressive motion (as in core cutting) or pass through one or more layers of material without contacting another tool surface. In burst cutting, the knife may be used in conjunction with a grooved roll, or it may be entirely free-cutting in a manner similar to razor-blade slitting.

Burst cutters are, by design and function, fairly thin knives. Material selection thus is restricted to alloys that are readily available in thin sheet, a group that includes 52100 steel, 1075 steel, and razor-blade stock. Except in those applications where resistance to elevated temperature is required (as in core cutting with a stationary blade), use of high-speed steels is rarely economical.

**Single knives, slicers, and disc knives** are used for cutting rolls of textile, foam, or film in a progressive fashion without unwinding (and rewinding) the roll.

*Single-knife cutters* are used to reduce wide rolls of paper, foam, or textile to narrower rolls without unwinding and rewinding. These knives have long, thin, one-sided or two-sided bevels, are kept sharp by means of one or more grinding wheels situated on the machine, and are activated either automatically (for grinding at specific intervals) or manually (for grinding as required).

Under normal circumstances, such knives are made from L2, L6, or D2 tool steel. Certain applications of single knives, including slicing of foam or impregnated fabrics, cause the thin bevel to heat up considerably as it penetrates the material being slit. In these cases, an alloy that has higher resistance to elevated temperatures, such as M2 or T1 tool steel, may be required. The choice may be restricted by availability of tool material or by production limitations. For instance, some single-blade slicer knives are 750 mm (30 in.) or more in diameter and would require heat treating facilities not generally available. Slicer knives are also particularly sensitive to flutter and straightness problems, so that selection of tool steel must be based on the ability to keep these factors within acceptable bounds.

*Slicer knives.* Group D, group M, and group T tool steels should be selected for slicer knives only where it is possible to use grinding wheels specifically intended for grinding materials other than standard group L tool steels. Large-diameter D2 knives, for instance, respond well to on-machine grinding with cubic boron nitride wheels, but these wheels represent a considerable investment and must be set accurately to achieve optimal performance from both wheel and knife.

### Straight Knives

**Types of straight knives** include trimmer knives, guillotine knives, sheeter knives, and cutoff knives.

*Trimmer and guillotine knives* are used for cutting one or more layers of material by virtue

of a bevel that exerts a downward force through the material.

*Sheeter knives and cutoff knives* are used in pairs for cutting roll stock into sheet or for cutting sheet to length. One or both of the knives in a pair can be mounted on a rotating drum or reciprocating holder. The lower (bed) knife frequently is stationary.

*Specialty Knives.* There are many other applications involving cutting of thin materials for which there is a wide variety of specially designed knives that do not fit into any of the foregoing categories. The selection of materials for specialty knives is not included in this article.

**The choice of material for a straight knife** is governed by several factors, including the cross section and length of the tool, production and maintenance facilities, and the cost of the knife itself.

A standard paper-trimmer knife consists of a carbon steel backing and an insert that provides the actual cutting edge. The backing, or carrier, remains soft after heat treatment. This allows the manufacturer or user of the knife to drill the necessary mounting holes without having to compensate for distortion during heat treatment and gives the knife a certain amount of shock resistance. The insert material can range from O1 to M2 to one of the group T high-speed steels. For most applications, O1 is ideal with respect to initial cost, ease of maintenance, and adequate performance between resharpenings. For cutting certain materials, such as coated papers, films, and foils, use of a more highly alloyed insert frequently can be justified in terms of quality of cut and service life, even though it may double the original cost of the knife. Trimmer knives also are available in solid steel, in which case the material is selectively hardened or induction hardened to produce a zone in which hardness diminishes from the cutting edge to the back of the blade. Care must be taken to ensure that a solid knife has uniform hardness along the entire length of the cutting edge and that the hardened zone is sufficiently deep to allow for numerous resharpenings. Such knives are considerably cheaper than insert-type knives but are also necessarily limited to steels that can be locally hardened.

Sheeter and cutoff knives are similar in function to trimmer knives and frequently are made with cutting-edge inserts of M2 high-speed steel hardened to 62 to 64 HRC. Under optimal conditions, life of these blades is very long—50 to 100 million cuts between resharpenings.

Some sheeter or cutoff blade designs are too narrow in cross section to allow for use of inserts; such knives are most often made of solid 52100, O1, or D2 tool steel.

## Selection of Material for Blanking and Piercing Dies

Blanking and piercing dies include the punches, dies, and related components used to

blank, pierce, and shape metallic and non-metallic sheet and plate in a stamping press. Blanking is a process of cutting by shear, as described in the articles “Principles of Shearing, Blanking, and Piercing” and “Blanking and Piercing” in this Volume. Sectional views of the blanking dies and the blanking and piercing punches used for making simple parts are shown in Fig. 16. Parts that are more complex require notching and compound dies.

Selection of tool material depends primarily on the number of acceptable parts to be produced by blanking and piercing. A common indication of tool deterioration is the production of a burr along the sheared edge of the workpiece. When tools are new, there is minimal clearance between punch and die, and the cutting edges are sharp. Under these conditions, the break in the stock begins at the underside (the side not in contact with the punch) because there the stock is subjected to the greatest tensile stress from stretching of the outer fiber. As more and more parts are produced, the cutting edges of the punch and the die become rounded by wear (Fig. 3), and the stress distribution in the stock is changed. Stress on the underside is reduced, breaking at that point is delayed, and deformation accompanied by work hardening occurs. When breaking starts, it nucleates from both sides simultaneously, and a burr develops on both the slug and the surrounding area of the sheet from which it was cut. The height of this burr increases with tool wear. Acceptable burr height varies with the application but is usually between 0.025 and 0.125 mm (0.001 and 0.005 in.).

Tool materials include tool steels, cemented carbides, steel-bonded carbides, or powder metallurgy tools (see “Tool Materials” in this article). Tool coatings are also instrumental in improving tool life, especially for high-volume blanking or piercing of thicker sections or high-strength sheet. Coating and surface treatments of tool steels are described in the section “Coatings and Surface Treatments” in this article.

**Tool Materials for Punches and Dies.** Table 5 lists typical materials for punches and dies used for blanking parts of different sizes and

degrees of severity from several different work materials about 1.3 mm (0.050 in.) thick in various quantities. Illustrations of typical parts are presented in Fig. 17. Typical materials for the punches and dies used to shave several work materials of this same thickness in various quantities are listed in Table 6.

Tables 5 and 6 can be used to select punch and die materials for parts made of sheet that is thicker or thinner than the 1.3 mm (0.050 in.) used for the parts illustrated in Fig. 17. For thicker sheet, the punch and die material recommended for the next greater production quantity should be used instead of the material recommended for the production quantity that will actually be made (in Tables 5 and 6, the column to the right of the production quantity that will actually be made). For thinner sheet, the punch and die material recommended for the next lower production quantity should be used instead of the material recommended for the production quantity that will actually be made (in Tables 5 and 6, the column to the left of the production quantity that will actually be made).

Table 7 lists typical materials for perforator punches used on several different work materials. The usual limiting slenderness ratio (punch diameter to sheet thickness) for piercing aluminum, brass, and steel is 2.5:1 for unguided punches and 1:1 for guided punches. For piercing spring steel and stainless steel, this ratio ranges from 3:1 to 1.5:1 for unguided punches and from 1:1 to 0.5:1 for accurately guided punches. Typical hardnesses for these perforator punches are given in Fig. 18.

Table 8 lists typical materials for perforator bushings of all three types (punch holder, guide or stripper, and perforator or die). These recommendations are particularly applicable to precision bushings—for example, where the outside diameter is ground to a tolerance of  $-0, +0.008$  mm ( $-0, +0.0003$  in.) and is concentric with the inside diameter within 0.005 mm (0.0002 in.) total indicator reading. The hardness of W1 bushings should be 62 to 64 HRC, and that of D2 bushings, 61 to 63 HRC.

**Fig. 16** Sectional views illustrating typical tools used for blanking and piercing simple shapes. Tooling at left is for short-run production of parts similar to parts 1 and 2 in Fig. 17 made from relatively thin-gage metal. Tooling at right is for longer production runs.

**Tool Materials for Die plates.** Die plates and die parts that hold inserts are usually made of gray iron, alloy steel, or tool steel. For stamping thick sheet or hard materials, either class 50 gray iron or 4140 steel heat treated to a hardness of 30 to 40 HRC should be used. For long-run die plates for stamping thick or hard materials, steels such as 4340 and H11 are preferred when inserts are pressed into the die plates, and 4340 is nearly always used when inserts are screwed in. Die plates for stamping thin or soft sheet can be made of class 25 or class 30 gray iron or carbon steel.

**Secondary Tooling.** Punch holders and die shoes for carbide dies are made of high-strength gray iron or low-carbon steel plate. Yokes for retaining carbide sections are usually made of O1 tool steel hardened to 55 to 60 HRC. Backup plates for carbide tools are preferably made of O1 hardened to 48 to 52 HRC. Strippers can

usually be made of low- or medium-carbon steel (1020 or 1035) plate. Where a hardened plate is used for medium-production work, 4140 flame hardened, W1 conventionally hardened, or W1 cyanided and oil quenched are often preferred. Hardened strippers for carbide dies and high-production D2, D4, or CPM 10V dies are made of O1 or A2, hardened to 50 to 54 HRC.

Custom-made hardened guides and locator pins are usually made of W1 or W2 for most medium- or long-run dies or of alloy steels such as 4140 for low-cost short-run dies. Commercial guide pins are often made of SAE 1117 and then carburized, hardened, and finished to a surface roughness of 0.4  $\mu\text{m}$  (16  $\mu\text{in.}$ ) rms.

**Applications of Specific Materials.** Rolled zinc alloy tooling plate is available in the form of 6.4 mm ( $1/4$  in.) plate from the principal suppliers of zinc-base die-casting alloys. Dies of this

material are sheared in with a flame-hardened O1 punch, and strippers of 9.5 mm ( $3/8$  in.) sheet cork are invariably used with them.

Tools of hot-rolled low-carbon steel plate (0.10 to 0.20% C) can be used for short runs of small parts if these tools have been surface hardened, either by carburizing to a depth of 0.25 to 0.50 mm (0.010 to 0.020 in.) or by cyaniding to a depth of 0.1 to 0.2 mm (0.004 to 0.008 in.). Because of distortion in heat treatment, use of this material is limited to the blanking of small, symmetrical shapes.

For the long-run blanking of soft materials, various sizes of aircraft-quality 4140 steel plate have been used. In this application, 4140 is normally flame hardened to about 50 HRC. Flame hardening the working edge of a large die has an advantage over through hardening in that very little warping or change of size occurs. However, tools with inside or outside corners

**Table 5 Typical punch and die materials for blanking 1.3 mm (0.050 in.) sheet**

Plastic sheet, reinforced	A2(f)	A2(f)	D2(f)	D2(f), CPM 10V	Carbide

Note: Although carbide is recommended in this table only for 10 million pieces, it should usually be considered also for runs of 1–10 million pieces. (a) Zn refers to a die made of zinc alloy plate and a punch of hardened tool steel. (b) For punching up to 10,000 parts, the W1 punch and die would be left soft and the punch peened to compensate for wear if necessary. (c) For punching 10,000–1,000,000 pieces, the W1 punch can be soft so that it can be peened to compensate for wear, or it can be hardened and ground to size. (d) Of the two alternatives listed, A2 tool steel is preferred if compound cooling is to be used for quantities of 10,000–1,000,000. (e) This O1 punch may have to be cyanided 0.1 to 0.2 mm (0.004 to 0.008 in.) deep to make even 1000 pieces. (f) For the application indicated, the punch and die should be gas nitrided 12 h at 540–565 °C (1000–1050 °F). (g) Soft. (h) Working edges are flame hardened in this application. (j) May be soft or flame hardened. (k) For punching 10,000–1,000,000 pieces, the punch would be W1, left soft so that it can be peened to compensate for wear, and the die would be O1, hardened. (m) Cyaniding of the punch is advisable, even for 1000 pieces. (n) For punching 10,000–1,000,000 pieces, the W1 die would be hardened and the W1 punch would be soft so that it can be peened to compensate for wear.

**Fig. 17** Typical parts of varying severity that are commonly produced by blanking and piercing. Parts 1 and 2 are relatively simple parts that require dies similar to those illustrated in Fig. 16. Parts 3 and 4 are more complex, requiring notching and the use of compound or progressive dies. Dimensions given in inches

**Table 6** Typical punch and die materials for shaving 1.3 mm (0.050 in.) sheet

Work material	Tool material for production quantity of:			
	1000	10,000	100,000	1,000,000
Aluminum, copper, and magnesium alloys	O1(a)	A2	A2	D4(b), CPM 10V
Carbon and alloy steel, up to 0.30% C, and ferritic stainless steel	A2	A2	D2	D4(b), CPM 10V
Carbon and alloy steel, 0.30–0.70% C	A2	D2	D2	D4(b), CPM 10V
Stainless steel, austenitic, up to quarter hard	A2	D2	D4(b)	D4(b), CPM 10V
Stainless steel, austenitic, more than quarter hard, and spring steel hardened to 52 HRC max	A2	D2	D4(b)	M2(b), CPM 10V

(a) Type O2 is preferred for dies that must be made by broaching. (b) On frail or intricate sections, D2 should be used in preference to D4 or M2. Carbide shaving punches may also be practical for this quantity.

**Table 7** Typical materials for perforator punches

(a) When bushings are of a shape that cannot be ground after hardening, an oil- or air-hardening steel is recommended to minimize distortion.

may have soft spots after flame hardening and, if so, will perform poorly.

The tool steels in Table 5 are assumed to have been hardened and tempered by conventional methods to their maximum usable hardness (58 to 61 HRC). In addition to these tool steels, type O6 has given satisfactory service in multiple-stage progressive dies, and type A10, because of its low austenitizing temperature, high dimensional accuracy, and good dimensional stability, is often used to make large dies for stamping laminations.

In some applications, M2 high-speed steel tools may produce smaller burrs than D2 tools (for equal numbers of parts). In addition, steel-bonded carbides and high-vanadium-carbide powder metallurgy tool materials such as CPM 10V should be considered for critical applications. Steel-bonded carbides (steel matrix with TiC) belong to the family of cemented carbide produced by powder metallurgy, but differ from cemented carbides in that the steel matrix can be altered by heat treatment. In the annealed conditions, steel-bonded carbides can be machined, then heat treated. As previously noted (see “Tool Materials” in this article), wear resistance is between that of tool steels and Co-WC cemented carbides.

Cemented tungsten-carbide tooling should be considered where production life must be four or more times that possible with D4 tool steel. Partial or complete carbide inserts in tool steel dies may be considered for lower quantities, especially where close tolerances and minimum burr height are desired or where tool life between resharpenings needs to be extended. However, brazed inserts are hazardous, and the cost of

**Fig. 18** Typical hardnesses for tool steel perforator punches. Regardless of material, punches should be tempered back to 56 to 60 HRC if they are to be subjected to heavy shock or used to pierce thick material.

dovetailed or mechanically held inserts approaches that of complete carbide dies.

Composition and hardness of carbides frequently used in blanking and piercing dies are as follows:

Composition, %			Hardness, HRA
W	C	Co	
75.1	4.9	20.0	86
78.9	5.1	16.0	86
81.7	5.3	13.0	88
88.3	5.7	6.0	91

The first material listed in the preceding table should be used where shock is appreciable. The second material combines toughness and wear resistance and is preferred for heavy-duty service, such as the piercing of silicon steel. Where close tolerances must be held in piercing silicon steel laminations, the third material is useful. The fourth material is best for guides and guide rolls and for applications involving very light shock. The data in Fig. 19 show that the difference in wear life between two different tool steels at the same hardness is negligible compared with the difference between the average life of conventional tool steel dies and the life of a carbide die or a CPM 10V die.

**Die life in the blanking and piercing of high-carbon steel** varies with different applications, depending greatly on the dimensional accuracy that must be maintained and the burr height that can be tolerated on the blanked parts. The most important difference between the blanking and piercing of high-carbon and of low-carbon steel is that greater clearance between punch and die is required for high-carbon steels (see Table 1 in the article “Blanking of Low-Carbon Steel” in this Volume).

Along with the increase in punch-to-die clearance, other tool changes are required for

efficiency in the blanking and piercing of high-carbon steel. The following examples illustrate various types of tooling changes for blanking high-carbon steel. The first example describes an application in which a change in tool material increased die life by a factor of about 28. The second example illustrates the common practice to have a punch mechanism with a second, chisel-pointed punch placed as close as possible to the blanking edge. With high-carbon steel (more so than with low-carbon steel), the scrap skeleton from blanking and piercing operations is likely, in springing back, to adhere to the punch, sometimes causing spalling of the punch edges. This second punch serves to spread the scrap skeleton, minimizing its adherence to the blanking punch (see example 2).

**Example 1: Change from Tool Steel to Carbide Punches and Dies.** The part shown in Fig. 20 was blanked and pierced from 48 mm (1 7/8 in.) wide coils of bright-finish 1045 steel having a hardness of 70 to 75 HR15N (equivalent to 20 to 30 HRC). Thickness ranged from 0.48 to 0.986 mm (0.019 to 0.0388 in.); tolerance for all thicknesses was +0.000, -0.03 mm (+0.000, -0.001 in.).

The punch and the die were both originally made of D2 tool steel at 62 to 63 HRC. To keep burr height on the parts at or below the maximum of 0.08 mm (0.003 in.), it was necessary to grind the die after each 25,000 pieces. The steel die had a usable depth of 16 mm (5/8 in.), and 0.20 mm

(0.008 in.) was removed with each grinding. Therefore, with 78 grindings, the total die life was 1.95 million pieces.

To improve die life, the tool material for both the punch and the die was changed to carbide. The carbide tools cost three times as much as the steel punch and die, but production between grinds increased to 350,000 pieces and only 0.10 mm (0.004 in.) of stock was removed per grind. Therefore, with the same amount of usable die, the total die life would be 54.6 million pieces.

The die was a compound-type unit. It was operated in a 445 kN (50 tonf) open-back inclinable mechanical press having a 75 mm (3 in.) stroke and mechanical feed.

**Example 2: Cost Reduction When Blanking Replaced Milling.** The blanked workpiece shown in Fig. 21 replaced a machined part of slightly different dimensions. For the machined part, starting blanks 75 mm (3 in.) long by 17 mm (1 1/16 in.) wide by 4.0 mm (5/32 in.) thick were sawed from ground flat stock of A2 tool steel spheroidize-annealed to 14 to 18 HRC. The long edges of the blanks were ground to reduce the width of the blank from 17 to 15.9 mm (1 1/16 to 0.625 in.). Grinding was followed by four separate milling operations. This change in production method from milling to blanking reduced machining time by an order of magnitude and decreased cost per piece by a factor of about 120 for 100 pieces.

The blanking was done in a 280 kN (32 tonf) open-back inclinable mechanical press with a punch and die made from A2 tool steel at 60 to 62 HRC. To obtain acceptable edges on the workpiece, a punch-to-die clearance of 8 to 10% of stock thickness per side was used. Because of the force required for stripping, it was necessary to add a chisel-edge punch to spread the scrap skeleton and to prevent damage to the blanking punch. In addition, a minimum corner radius of 1.6 mm (0.062 in.) was necessary for efficient stripping, and the overall width of the part was increased to 17.7 mm (0.696 in.).

# Trimming Operations

FOR MANY TYPES of stamped parts, excess metal must be allowed for holding purposes during operations that shape the metal into the form of the part. This excess metal must, of course, be removed; such removal is done by trimming. Trimming is the removal of excess metal from a stamped part to allow the part to reach the finished stage or to prepare it for subsequent operations. For nearly all parts requiring drawing operations, trimming is necessary. Formed parts other than those produced from fully developed blanks also must undergo some trimming before they are brought to final size.

## Analysis of Parts to be Trimmed

Trimming of a part is usually performed immediately after a drawing operation. Therefore, it is necessary to consider what the part will look like after it is removed from the drawing die.

The process engineer must provide answers to many questions, such as:

- Should the part be trimmed open side up or open side down?
- Can the part be trimmed in one operation, or should it be trimmed in two operations?
- Is it necessary to separate two or more pieces if parts are made in multiples?
- Is any notching required?
- Are both rough and finished trimming needed?
- Should two trimming dies be built, or can a cam trimming die be used?
- Are there any operations that can be combined with trimming?

A plan view of a plaster model can reveal that the shape of the trim outline that is going to require external cutting will be square, rectangular, oval, irregular but symmetrical, or irregular and nonsymmetrical (Fig. 1). A side elevation view may reveal that the binder metal is in a flat plane, has a single contour, or has multiple contours.

Internal cutting may also be required on the panel if it is necessary to separate parts (such as for the right-hand and left-hand sides of a car) or if large openings must be made somewhere in the panel for the purpose of allowing an extruded

section to be made such as a window opening, a lightening hole, or an access hole.

The thickness of the metal to be cut may have some bearing on the trimming operation. In addition, consideration must be given to the possible creation of knifelike edges on the part that might injure employees who must handle the panels in later operations.

## Selection of Trimming Dies

Due to the wide variety of stamped parts, a number of different types of trimming dies have been developed. The edge requirements and size of the part will generally indicate what kind of die should be used.

### Conventional Trimming Dies

The **flush trimming die** is the type of die most widely used in automotive stamping (Fig. 2). This type of die has two opposing cutting steels, operating much in the same fashion as a pair of scissors, that cut vertically on the downstroke of the press. The part is usually supported open side down on a solid pad mounted on the lower shoe; this pad is very similar to the

type used on a solid forming die. There is usually a spring-loaded pad fastened to the punch. This pad holds the part firmly in position on the downstroke of the press. The upper cutting steels surrounding the spring pad contact the part after the pad has descended, and the scissors-like action takes place when the upper trimming steels pass by the lower trimming steels. After the press has completed its cycle, the part is ejected or lifted out of the die. Flush trimming results in a small burr around the edge of the cut because of the necessary clearance allowed between the punch and die.

The location of this burr is frequently important in flanging the part in later operations. The burr may be located on the top or the bottom of the flange depending on the position of the part in the die. If the part is positioned open side up, the burr will be on the underside of the flange. If the part is inverted, the burr will be located on the top of the flange.

After the press has completed its cycle, the metal cut away from the part, which is the offal, is usually in the form of a ring. This material must be disposed of in one way or another. If allowed to remain in ring form, it would require manual or mechanical removal from the die. To avoid this, scrap cutters are designed and built as integral units of the lower trimming steels. These are knifelike blades mounted perpendicular to the trim line. Mating steels are also mounted on the punch. These scrap cutters are usually designed to part the material at distances from 305 to 455 mm (12 to 18 in.), as described

Fig. 1 Trim line on plaster die model

Fig. 2 Flush trimming die

later. Provision is made for disposal of this stock in the design of the die and layout of the press department.

A **parting trimming die** is used for separating two or more parts formed or drawn from a single sheet of metal (Fig. 3). The cutting steels in these dies must be accurately aligned, and the parts must be firmly held during cutting to ensure that separation is accomplished at exactly the right place. Usually when parts are separated, a thin strip of metal is cut from between them. Consideration must be given to the removal of this scrap metal. Parting is frequently combined with flush trimming.

A **horn trimming die**, which is sometimes called a "hang-up" die, is a die generally mounted on a horn-type press that has an overhanging mechanism for separating the slide. The die is mounted on the front of the press. A portion of the part hangs over the die, and then the press is cycled. Such dies are generally used when trimming of relatively short length is involved.

### Cam Trimming Dies

A cam trimming die (Fig. 4) may be used where the operation cannot be performed entirely with a vertical stroke of the press. One or more cams are used to convert the vertical action of the ram into an action in a more suitable direction, such as  $70^\circ$ ,  $85^\circ$ ,  $90^\circ$ , or some other angle. The use of cams, while providing perhaps the only solution to a difficult trimming application, poses certain problems for pressworking. These problems should be thoroughly considered before a final decision to employ a cam trimming die is made. A cam die is justified if a saving in piece price can be achieved or if a limited number of presses are available for running the parts, which would necessitate the combination of cams on a flush trimming die. The design of the cam mechanism must be such that parts can be loaded and unloaded without interference. Provision must be made for easy removal of scrap generated by the cam trimming steels. Cam construction must be done with consideration of employee safety. Cams should be located where they are not in the way of the employee. Where

cams move out from the press bed, guards should be installed to prevent injury to plant personnel.

The cam slide contains the cutting steel and is guided by steel gibs with hardened steel wear plates. Provision should be made for shimming of the wear plates to adjust the clearance of the cutting tools to compensate for wear.

A **cam mounted on the die** is usually driven by a wedge-shape driver attached to the punch. The action is obtained by a wedge-shape block on the cam. On the upstroke of the press, the cam is returned by springs or by an air cylinder. In some cases, the advance and return of the cam are accomplished with a positive-type driver that is designed with several offsets to accomplish the desired action. Stop

blocks are used to limit the back travel of the cam. The back travel must be great enough, however, to permit easy loading and unloading of parts.

A **cam mounted on the punch** is used for certain applications where the path of cam action is between perpendicular and  $45^\circ$  from the vertical action of the press. Such a cam will float on the punch and is actuated by a driver mounted on the die.

A **shimmy trimming die**, which is a form of cam trimming die, is often used in trimming cup-shape parts where exceptionally clean cut edges are required. In this type of die, when it is desired to trim the part open side up, the part is pushed into position by the ram of the press. A lower floating die, activated by positive-motion

Fig. 3 Parting trimming dies used to separate parts drawn in multiples

Fig. 4 Cam trimming dies

cams mounted on the punch, reciprocates from side to side and from front to back to trim the part. If it is desired to trim the part open side down, the floating section may be mounted on the upper shoe with the drivers on the lower shoe.

A **pinch trimming die** is frequently used for trimming cup-shape parts with only the vertical action of the press (Fig. 5). This operation is often combined with a drawing operation and may even be combined with blanking. In such a compound die, the punch first draws the part to the proper depth. After this, the punch continues its travel, and the flange is pinched off by the action of the cutting steels on the punch against the cutting steels on the die. Clearances between punch and die must be held to a minimum to ensure an even pinch-off. Although every effort is made to prevent the formation of ragged edges on the trim line, such an objective is seldom obtained with a pinch-trimming die.

## Rough and Finish Trimming

**Rough Trimming.** There are instances in which certain areas of a part may be trimmed away prior to completion of other operations. This is called rough trimming, because the edge produced will not be the final edge of the part.

Rough trimming is often done prior to a restriking operation. Restriking operations have as their purpose the final sizing of the curved areas of drawn parts. The rough trimming is necessary to prevent the scrap around the part from restricting metal movement or causing springback.

Rough trimming is used in other instances to permit convenient handling of a part after a first drawing operation. This is particularly true of large panels drawn from square-sheared stock, where large holding flanges represent a hazardous and awkward handling problem.

Rough trimming may also be necessary when a very large amount of scrap must be cut away. Cutting all the scrap in one finish trimming operation may cause problems in removing the

scrap from the die. In such a case, a portion of the scrap may be trimmed off in one operation and the part finish trimmed in another operation. This may provide a more suitable arrangement and a solution to the scrap-disposal problem.

**Finish trimming** generally is done as the final operation in bringing a part to final size. The location of the rough trim line in relation to the finish trim line is of major importance in setting up a rough trimming operation. If insufficient metal is left for finish trimming, the finish cut will not be clean. An excessively narrow strip of metal will crush or draw down during trimming, leaving chips or hairlike burrs. In most cases, these chips or burrs will be deposited on the die surface, causing trouble in later operations. The chips will build up on the die, causing scoring of parts and injury to the die. Generally speaking, at least 3 mm ( $1/8$  in.) of metal should be left for removal in a finish trimming operation to avoid burrs and chips.

## Construction Details of Trimming Dies

The production of parts to specifications is the primary consideration in the construction of a trimming die. Before die design is begun, the shape and contour of the finished part (as shown by part print, prototype model, and die model) are carefully considered. The locations of holes and their proximity to the trim line are noted. If holes are too close to the trim line, distortion or breakage may occur unless provision is made for proper holding. The shape and contour of the part will also provide clues as to the amount of metal that will be provided for holding during operations preceding trimming and will indicate the amount of metal that will be left for trimming.

Die design must also be considered in relation to the specifications of the press to be used. A determination is made as to whether the press has the proper shut height and area to accommodate the die needed for trimming, and whether it will accommodate the stamping with the binder scrap attached. Consideration is also given to the possibility of designing a die that will be amenable to automation once it is installed in the press.

There are numerous details that must be worked out in the design and construction of a trimming die if proper performance is to be obtained. Although many of these details are of interest only to the die designer and diemaker, several should also be of concern to the process engineer.

One of the factors influencing construction of trimming dies is the extreme care that must be given to the guiding of cutting tools. While some side thrusts and unbalanced conditions may be tolerated in forming or drawing operations, positive guiding in trimming operations is imperative because of the necessity for proper mating between the upper and lower cutting

steels. If cutting steels are not properly aligned, they will certainly suffer damage caused by the opposing edges striking together. To guard against such damage, guide pins are used to ensure accurate travel of the moving member of the die. Trimming dies for small parts may be adequately guided by two guide pins. For larger parts, more pins (up to four) may be required. These guide pins are supplied whether or not the cutting job to be done is evenly balanced.

In cases where unbalanced forces are present in trimming, heel blocks should be used to absorb the side thrust. These heel blocks consist of built-up steel bearing surfaces usually located at all four corners of the die. Ordinarily mounted on the lower die or die shoe, the blocks restrain the punch from moving sideways as it descends. This provision prevents tool breakage and helps to ensure a satisfactory edge on the trimmed part. It is important to locate heel blocks so that they will not interfere with loading or unloading of parts.

The selection of steels for trimming dies will depend on the complexity of the operation and the production volume involved.

The shoes for trimming dies are made of the same material as the other dies in the press lines. The cutting steels on both the punch and die are usually made of composite sections rather than from solid steel blocks, because it is easier to mount the sections at various angles on the mounting blocks and to remove them for resharpening.

As in all types of cutting, the pressure requirements in trimming operations can be reduced by grinding shear on the cutting edges of the tools. In trimming, the shear is ground on the punch. The shear may be either balanced or unbalanced. Where a long cut is to be made, it is generally advantageous to provide balanced shear to reduce the tendency of the blank to shift in the die.

Another consideration in setting up trimming operations is the clearances provided between the cutting steels. If insufficient clearance is allowed, the edges will be ragged. Secondary shearing will take place, adding to the load on the press and the wear on the cutting steels. Excessive clearance will cause the edge of the cut to draw down, leaving a burred edge. Many of the same clearances for piercing operations apply generally to trimming.

When parts are trimmed, there is a tendency for them to stick to the sides of the cutting tools. To prevent the edges of the part from lifting up and perhaps buckling as the punch ascends, strippers are provided. These strippers are usually spring-powered. Springs must be strong enough to strip the part from the cutting steels.

Trimming operations call for relatively close observance of tolerances. To ensure that tolerances are met, the part being trimmed must be accurately and firmly located in the dies. Special locators are placed over spacer plates where necessary for locating the part. If the shape of the part is not conducive to locating, pin locators

**Fig. 5** Pinch-trimming die for combined drawing and trimming

or gages may be used in holes in the part. Gages should be adequate for holding the part firmly. Proper gaging (locating) is vital to accurate and fast trimming operations. Stripper plates frequently assist in holding the part by contacting the work prior to the cutting action.

## Selection of Presses for Trimming

Because of the requirements for exceptional control and relatively high precision, special care must be exercised in selection of a press for a trimming operation. The press as well as the die must be equipped to ensure accurate mating of the cutting steels. Older presses should be examined carefully to make certain they will provide good alignment.

**Gap-frame presses** are frequently used for trimming small or medium-size parts in a wide range of volume requirements. Because of their accessibility, they are particularly adaptable to the use of automation for handling of parts. Such presses are usually of the inclinable type, and thus gravity can be utilized to facilitate unloading.

There are, however, certain features of gap-frame presses that may serve to complicate trimming operations if press adjustments are not made. The feature of these presses that is most important is their gap construction. This gap tends to deflect, and spring open, under prolonged use and/or heavy loading. Where trimming is involved, this factor has important implications for the maintenance of the punch and die.

The deflection tends to cause the edges of the cutting steels to contact each other, resulting in breakage or undue wear. To counteract this disadvantage, tie rods may be installed across the gap to give the press greater rigidity. Another means of minimizing this problem is to employ presses of greater tonnage than is required by the cutting operation involved. This is called a press tonnage safety allowance and is a frequently used solution to the problem of deflection.

Guiding and stabilization of the press slide itself is another important factor. In addition to carefully aligned gibs on the press, guide pins and heel blocks should be provided in the die itself.

**Straight-Side Presses.** Deflection is more easily controlled in a straight-side press, where gibs at all four corners of the press are frequently used. The gibs tend to neutralize any side thrusts caused by uneven cutting pressures. Presses with two- and four-point suspension resist deflection from unequal loading. Nevertheless, heel blocks are often used in trimming dies run in four-column straight-side presses.

## Scrap Handling

The handling and disposal of scrap have an important bearing on the efficiency of trimming

operations. In any trimming application, some scrap or offal is generated. Provision must be made for removal of this material from the area of press.

**Implications for Overall Press Operations.** Removal of scrap in trimming operations has implications for the total effectiveness of all press operations. If adequate means of scrap disposal are not provided, an entire stamping operation could be easily bogged down. The removal of scrap often determines the speed of a trimming operation, and trimming speed often governs the entire press line. Thus, adequate facilities for scrap removal constitute one of the initial considerations in establishing effective stamping operations. In addition to the scrap involved in trimming, thought must also be given to the removal of scrap from blanking, piercing, and other types of cutting operations.

There are two aspects of the problem of scrap removal that stand out. One is the removal of scrap from the die itself, and the other is the removal of scrap from the area of operations. Several principles for solving these problems have been worked out. Consideration is given to some of the steps that should be taken.

**Scrap Size.** One of the first steps in effective scrap handling is to reduce the scrap to manageable size. Trimming involves cutting away portions of material that vary considerably with respect to size. The size of scrap will determine the ease with which it may be removed from the die and also from the press area. The maximum size of scrap that can be handled successfully is 610 mm (24 in.) in length. Smaller pieces are preferable. A length of 455 mm (18 in.) is considered to be optimum for most efficient removal from the press and from the work area.

**Removal of Scrap from Dies.** The methods to be used in removing trimmings and other scrap from dies should be planned concurrently with die design. This will permit the designer and the process engineer to make certain that adequate space is allowed for any die attachments necessary for removing scrap.

The die should be designed with sufficient height to allow the scrap to fall away from the die surface. This height will depend on the size of scrap and the provisions for receiving it outside the press.

In many cases, chutes should be incorporated in the die to carry the scrap to stock boxes or conveyors. The chutes should be designed to provide ample space for trimmings to fall through. If trimmings become wedged in a chute, the press will have to be shut down until they are cleared. In some cases, the design of the die will permit the scrap to fall directly into stock boxes without the use of chutes. It is necessary that the die design allow each piece of scrap to be completely removed from the die area, or at least to a space where it can be allowed to pile up for occasional removal. Operating speed is seriously reduced in cases where operators must clear away scrap after each press cycle.

Where scrap is large, or where it is trimmed from all around the part, scrap cutters should

be provided to reduce it to manageable size. These cutters should be provided with shear to reduce load requirements. They should also be installed with consideration of possible changes in the binder surface of the die.

It is sometimes difficult to direct the fall of scrap to the proper area. This is particularly true of internal trimmings that fall through the die. To remove this type of scrap, small conveyors may be used. These may be of the belt variety, or, where trimmings are very small and tend to slip under a belt, vibration-type conveyors may be used.

**Removal of Scrap from Work Area.** The most effective means of removing scrap from the work area is to shed it through chutes to a conveyor that will move it directly to the scrap baler. This conveyor is usually situated under the press floor and away from the stamping operations. Where it is unfeasible to use this system, scrap bins or trailers can be used. These too, can often be located in a basement area where they will not interfere with work on the press floor. When these bins and containers are filled, they are taken away to the baler by industrial trucks and empty containers are substituted.

**Use of Scrap and Offal.** The metal cut away from parts in trimming and blanking operations is often referred in press-room terminology as either scrap or offal. While there is no particular distinction between these two terms in standard dictionaries, each has a special meaning for the process engineer and each serves an important purpose in overall company operations.

Offal is generally considered to be the type of trimmings that can be put to further use in the stamping plant. This material is often used for making small parts in low-, medium-, and in some cases high-volume production. Since offal usually is unevenly shaped, hand methods of feeding it to blanking presses are generally used. An operator, by using good judgment, can often obtain good blanks from a large percentage of a piece of offal. Offal is also used as blanks for some small parts that can be successfully blanked and formed from the material in one operation. A process engineer, by giving attention to the trimmings that must be cut away from some parts, can often find means of achieving significant material economy by using the trimmings for producing other stampings.

Many trimmings, especially those from deeply drawn parts, are wrinkled and distorted, and it is impractical to use them in further operations. Other trimmings are too small or too oddly shaped to lend themselves to further use in stamping. Such material is baled and returned to the steel plant where it is used as the very necessary scrap charge in making new steel.

## Material Handling in Trimming

**Automatic Loading.** Trimming frequently sets the pace for a group of related press

Fig. 6 Combined trimming and piercing

operations, and thus it is important that trimming dies be built to meet the production-volume requirements of the part. One method of attaining satisfactory speed in a press operation is to cut down the time required for loading the press. While loading takes place, the press is idle. Reduction in loading time can therefore yield a higher degree of utilization of press capacity. To reduce loading time, consideration should be given to the use of automatic loading devices. This possibility should be considered during construction of the die so that space can be allowed for any necessary attachments. For small

Fig. 7 Combined trimming and flanging

parts, an automatic loading device may consist of a simple gravity slide that will bring the part to rest properly in the die. For larger parts, a shuttle conveyor may be used.

**Automatic Unloading.** Another means of reducing waiting time in press operations is to provide speedy automatic means of unloading parts. For small parts, air blasts should be used. For medium parts, an effective unloading system may use lifters to free the part from the die and a positive kicker to eject the part. Provision may also be made in some cases to use the incoming part as an effective tool for forcing the completed

part out of the die. Where parts are very large, iron hands are frequently used to extract them. To expedite handling, belt conveyors or stock boxes should be used to receive the parts as they issue from the die.

## Combined Operations

Trimming operations are frequently combined with other types of cutting operations that must for various reasons follow the drawing of a part. Some forming operations also may be successfully combined with trimming.

**Trimming and Piercing.** Drawn parts frequently must be pierced after drawing in order for the holes not to be deformed. In these cases, it is economical to combine the piercing and trimming operations (Fig. 6). Holes may be pierced in the flange of a drawn part in the same die that trims the flange.

**Trimming and flanging** are also frequently combined (Fig. 7). The trimming is accomplished first as the punch depresses the part on a spring pad. When trimming is completed, the punch continues down and forms the flange. Trimming is also combined with many other types of operations.

# Oxyfuel Gas Cutting

OXYFUEL GAS CUTTING (OFC) includes a group of cutting processes that use controlled chemical reactions to remove preheated metal by rapid oxidation in a stream of pure oxygen. A fuel gas/oxygen flame heats the workpiece to ignition temperature, and a stream of pure oxygen feeds the cutting (oxidizing) action. The OFC process, which is also referred to as burning or flame cutting, can cut carbon and low-alloy plate of virtually any thickness. Castings more than 760 mm (30 in.) thick commonly are cut by OFC processes. With oxidation-resistant materials, such as stainless steels, either a chemical flux or metal powder is added to the oxygen stream to promote the exothermic reaction.

The simplest oxyfuel gas cutting equipment consists of two cylinders (one for oxygen and one for the fuel gas), gas flow regulators and gages, check valves, flashback arrestors, gas supply hoses, and a cutting torch with a set of exchangeable cutting tips. Such manually operated equipment is portable and inexpensive. Cutting machines, employing one or several cutting torches guided by solid template pantographs, optical line tracers, numerical controls, or computers, improve production rates and provide superior cut quality. Machine cutting is important for profile cutting, that is, the cutting of regular and irregular shapes from flat stock.

## Principles of Operation

Oxyfuel gas cutting begins by heating a small area on the surface of the metal to the ignition temperature of 760 to 870 °C (1400 to 1600 °F) with an oxyfuel gas flame. Upon reaching this temperature, the surface of the metal will appear bright red. A cutting-oxygen stream is then directed at the preheated spot, causing rapid oxidation of the heated metal and generating large amounts of heat. This heat supports continued oxidation of the metal as the cut progresses. Combusted gas and the pressurized oxygen jet flush the molten oxide away, exposing fresh surfaces for cutting. The metal in the path of the oxygen jet burns. The cut progresses, making a narrow slot, or kerf, through the metal.

To start a cut at the edge of a plate, the edge of the preheat flame is placed just over the edge to heat the material. When the plate heats to red, the cutting oxygen is turned on, and the torch moves over the plate to start the cut.

During cutting, oxygen and fuel gas flow through separate lines to the cutting torch at pressures controlled by pressure regulators, adjusted by the operator. The cutting torch contains gas ducts, a mixing chamber, and valves to supply an oxyfuel gas mixture of the proper ratio for preheat and a pure oxygen stream for cutting to the torch tip. By adjusting the control valves on the torch handle or at the cutting machine controller, the operator sets the precise oxyfuel gas mixture desired. Depressing the cutting-oxygen lever on the torch during manual operation initiates the cutting-oxygen flow. For machine cutting, oxygen is normally controlled by the operator at a remote station or by numerical control. Cutting tips have a single cutting-oxygen orifice centered within a ring of smaller oxyfuel gas exit ports. The operator changes the cutting capacity of the torch by changing the cutting tip size and by resetting pressure regulators and control valves. Because different fuel gases have different combustion and flow characteristics, the construction of cutting tips, and sometimes of mixing chambers, varies according to the type of gas.

Oxyfuel gas flames initiate the oxidation action and sustain the reaction by continuously heating the metal at the line of the cut. The flame also removes scale and dirt that may impede or distort the cut.

The rate of heat transfer in the workpiece influences the heat balance for cutting. As the thickness of the metal to be cut increases, more heat is needed to keep the metal at its ignition temperature. Increasing the preheat gas flow and reducing the cutting speed maintains the necessary heat balance.

Oxygen flow also must increase as the thickness of the metal to be cut increases. The jet of cutting oxygen must have sufficient volume and velocity to penetrate the depth of the cut and still maintain its shape and effective oxygen content.

**Quality of Cut.** Oxyfuel gas cutting operations combine more than 20 variables. Suppliers of cutting equipment provide tables that give approximate gas pressures for various sizes and styles of cutting torches and tips and recommended cutting speeds; these variables are operator controlled. Other variables include type and condition (scale, oil, dirt, flatness) of material, thickness of cut, type of fuel gas, and quality and angle of cut.

Where dimensional accuracy and squareness of the cut edge are important, the operator must adjust the process to minimize the kerf, the width of metal removed by cutting, and to increase smoothness of the cut edge. Careful balancing of all cutting variables helps attain a narrow kerf and smooth cut edge. The thicker the work material, the greater the oxygen volume required and therefore, the wider the cutting nozzle and kerf.

## Process Capabilities

Oxyfuel gas cutting processes are used primarily for severing carbon and low-alloy steels. Other iron-base alloys and some nonferrous metals can be oxyfuel gas cut, although process modification may be required, and cut quality may not be as high as is obtained in cutting the more widely used grades of steel. High-alloy steels, stainless steels, cast iron, and nickel alloys do not readily oxidize and therefore do not provide enough heat for a continuous reaction. As the carbon and alloy contents of the steel to be cut increase, preheating or postheating, or both, often are necessary to overcome the effect of the heat cycle, particularly the quench effect of cooling.

Some of the high-alloy steels, such as stainless steel, and cast iron can be cut successfully by injecting metal powder (usually iron) or a chemical additive into the oxygen jet. The metal powder supplies combustion heat and breaks up oxide films. Chemical additives combine with oxides to form lower-temperature-melting products that flush away.

**Applications.** Large-scale applications of oxyfuel cutting are found in shipbuilding, structural fabrication, manufacture of earth-moving equipment, machinery construction, and in the fabrication of pressure vessels and storage tanks. Many machine structures, originally made from forgings and castings, can be made at less cost by redesigning them for OFC and welding with the advantages of quick delivery of plate material from steel suppliers, low cost of oxyfuel gas cutting equipment, and flexibility of design.

Structural shapes, pipe, rod, and similar materials can be cut to length for construction or cut up in scrap and salvage operations. In steel mills and foundries, projections such as caps, gates, and risers can be severed from billets and

castings. Mechanical fasteners can be quickly cut for disassembly using OFC. Holes can be made in steel components by piercing and cutting. Machine OFC is used to cut steel plate to size, to cut various shapes from plate, and to prepare plate edges (bevel cutting) for welding.

Gears, sprockets, handwheels, clevises and frames, and tools such as wrenches can be cut out of wrought materials by oxyfuel gas torches. Often, these oxyfuel-cut products can be used without further finishing. However, when cutting medium- or high-carbon steel or other metal that hardens by rapid cooling, the hardening effect must be considered, especially if the workpiece is to be subsequently machined.

**Thickness Limits.** Gas can cut steels less than 3.2 mm ( $1/8$  in.) thick to over 1525 mm (60 in.) thick, although some sacrifice in quality occurs near both ends of this range. With very thin material, operators may have some difficulty in keeping heat input low to avoid melting the kerf edges and to minimize distortion. Steel under 6.4 mm ( $1/4$  in.) thick often is stacked for cutting of several parts in a single torch pass.

There are a number of advantages and disadvantages when OFC is compared to other cutting operations such as arc cutting, milling, shearing, or sawing. The advantages of OFC are:

- Metal can be cut faster by OFC. Setup is generally simpler and faster than for machining and approximately equal to that of mechanical severing (sawing and shearing).
- Oxyfuel gas cutting patterns are not confined to straight lines as in sawing and shearing, or to fixed patterns as in die cutting processes. Cutting direction can be changed rapidly on a small radius during operation.
- Manual OFC equipment costs are low compared to machine tools. Such equipment is portable and self-contained, requiring no outside power and well suited for field use.
- When properties and dimensional accuracy of gas cut plate are acceptable, OFC can replace costly machining operations. It offers reduced labor and overhead costs, reduced material costs, reduced tooling costs, and faster delivery.
- With advanced machinery, OFC lends itself to high-volume parts production.
- Large plates can be cut quickly in place by moving the gas torch rather than the plate.
- Two or more pieces can be cut simultaneously using stack cutting methods and multiple-torch cutting machines.

The limitations of the OFC process include:

- Dimensional tolerances are poorer than for machining and shearing.
- Because OFC relies on oxidation of iron, it is limited to cutting low-alloy steels without the use of powder or flux additions to the cutting oxygen.
- Heat generated by OFC can degrade the metallurgical properties of the work material adjacent to the cut edges. Hardenable steels may require preheat and/or postheat to control

microstructural and mechanical properties and to avoid cracking.

- Preheat flames and the expelled red hot slag pose a very real fire hazard to plant and personnel.

Oxygen consumption and flow rates vary depending on whether economy, speed, or accuracy of cut is desired. For average straight-line cutting of low-carbon steel, consumption of cutting oxygen per pound of metal removed varies with thickness of the metal and is lowest at a thickness of 100 to 125 mm (4 to 5 in.).

By assuming that for every unit mass of iron oxidized an equal mass of iron melts, one can calculate the amount of heat generated by the cutting reaction—heat emitted is 6680 kJ/kg (2870 Btu/lb) of iron oxidized. Melting of 0.5 kg (1 lb) of iron takes 715 kJ (680 Btu), based on a melting point of 1540 °C (2800 °F), 0.8 kJ/kg · K (0.2 Btu/lb · °F) as the specific heat, and 272 kJ/kg (117 Btu/lb) as the heat of fusion. Only a small amount of the heat melts the iron; most of it, approximately 4900 kJ/kg (2100 Btu/lb), goes into the reaction. Some of this superheats the molten metal, some soaks into the workpiece, and some leaves by radiation and convection. Most of it leaves with the slag and hot exhaust gases.

As cutting oxygen flows down through the cut, the quantity available for reaction decreases. If the flow of oxygen is large and well collimated, the rate of cutting through the depth of the cut is approximately constant. The cutting face remains vertical if the oxygen is in excess and if cutting speed is not excessive.

If oxygen flow is insufficient, or cutting speed too high, the lower portions of the cut react more slowly, and the cutting face curves behind the torch. The horizontal distance between point of entry and exit is called drag (Fig. 1).

Drag influences edge quality. Optimal edge quality results from zero drag—the oxygen stream enters and leaves the cut in a straight line along the cutting tip axis. This is called a drop-cut, designating a clean, fully severed edge. Increasing cutting speed or reducing oxygen flow makes less oxygen available at the bottom of the cut, causing the bottom of the cut to “drag” behind the top of the cut. A drag of 20% means that the bottom of the cut edge lags the top surface by 20% of the material thickness. Drag lines appear as curved ripples on the cut edge. For fast, rough cuts, some drag is acceptable.

Drag is a rough measure of cut quality and of economy in oxygen consumption. In metal thicknesses up to 50 to 75 mm (2 or 3 in.), 10 to 15% drag indicates good quality of cut and economy. The key to quality cuts is control of heat input. Higher quality demands less drag; more drag indicates poorer quality and low oxygen consumption. Excessive drag may lead to incomplete cutting.

In very thin sections, drag has little significance. In very thick sections, the goal is to avoid excessive drag.

Preheating may consist of merely warming a cold workpiece with a torch or may require furnace heating of the work beyond 540 °C (1000 °F). For some alloy steels, preheat temperatures are 205 to 315 °C (400 to 600 °F). Carbon steel billets and other sections occasionally are cut at 870 °C (1600 °F) and higher. As is the case in welding, the carbon equivalent of the steel being cut is a major factor in determining the need for preheating.

In OFC, preheating is accomplished by means of the oxyfuel gas flame, which surrounds the cutting-oxygen stream. At cut initiation, the preheat flame, the result of oxygen and fuel gas combustion, brings a small amount of material to ignition temperature so that combustion can proceed. After cutting begins, the preheat flame merely adds heat to compensate for heat lost by convection and radiation or through gas exhausted during cutting. The flame also helps to remove or burn off scale and dirt on the plate surface; the hot combusted gases protect the stream of cutting oxygen from the atmosphere.

Preheating may also be applied over a broader area of the work. It may include soaking the entire workpiece in a furnace to bring it up to 95 to 205 °C (200 to 400 °F), or a simple overall warmup with a torch to bring cold plate to room temperature. A preheat improves cutting speed significantly, allowing faster torch travel for greater productivity and reduced consumption of fuel gas. Broader preheat smooths the temperature gradient between the base metal and the cut edge, possibly reducing thermal stress and minimizing hardening effects in some steels.

## Properties of Fuel Gases

Each cutting job entails a different type or volume of work to be completed. Consequently, the best gas for all cutting in a fabricating plant is found through experimentation. Evaluating a gas for a single job requires a test run that monitors fuel gas and oxygen flow rate, labor costs, overhead, and the amount of work performed. If plant production varies from week to week, gas performance should be measured over a long enough period to achieve an accurate cost

**Fig. 1** Schematic cross section of work metal during oxyfuel gas cutting showing drag on cutting face

analysis. Any of the fuel gases may perform well over a range of flow rates. When comparing gases, performance should be rated at the lowest flow rate that gives acceptable results for each gas.

Gas manufacturers provide comprehensive data on flame temperature, heat of combustion, oxygen-to-gas consumption ratio, heat transfer, and heat distribution in the flame. Gas properties can be rated on a weight or volume basis. Flow rates, for example, commonly are given in terms of volume. Gas may be sold, however, by weight or by volume, and specifications may state properties in terms of one or the other to make the product seem as attractive as possible. For example, acetylene occupies more volume per pound than does propane. Consequently, cost based on weight makes propane liquid seem inexpensive. Cost based on volume makes the lighter fuels, such as acetylene, seem less costly. The user must understand these ratings and comparisons.

**Heat Distribution in the Flame.** Combustion of fuel gas produces the preheat flame, which initiates cutting action and helps sustain the operation. These flames heat the surface of the work to ignition temperature to (1) initiate cutting, (2) descale and clean the work surface, (3) supply heat to the work and the cutting-oxygen stream to maintain the heat needed for continuous cutting, and (4) shield the cutting-oxygen stream from surrounding air. Preheat gases consist of hydrocarbons, which produce water vapor and carbon dioxide as products of chain reactions. These reactions occur in cones within the flame, usually visible as an inner and outer flame. A gas whose inner flame has a high temperature and high heat release provides the most concentrated heat. These gases are superior for fast starts in flame cutting of high-alloy steels that are difficult to cut.

When low heat release is accompanied by high flame temperature, even though it is above the melting point of steel, heat is diffused and gives slow starts in flame cutting. Gases, such as natural gas, that release most of their heat in the outer flame are well suited to heating and heavy cutting. Heat distribution is a good indication of the potential performance of a particular gas.

## Fuel Types

**Acetylene** ( $C_2H_2$ ) is the most widely used cutting gas. It burns hotter than any of the other common fuel gases, making it indispensable for certain jobs. Despite some disadvantages, acetylene has been used for cutting for a longer time than any other gas. Its performance is well understood, equipment for its use is perfected and widely marketed, and it is readily available. It has become the standard against which all other gases are compared.

Acetylene combustion produces a hot, short flame with a bright inner cone at each cutting-tip port; the hottest point is at the tip of this inner cone. Combustion starts in the inner cone and is

brought to completion in a cooler, blue, outer flame. The sharp distinction between the two flames helps the cutting operator to adjust the ratio of oxygen to acetylene.

Depending on this ratio, the flame may be carburizing (reducing), neutral, or oxidizing. A neutral flame results when just enough oxygen is supplied for primary combustion, yielding carbon monoxide (CO) and hydrogen ( $H_2$ ). These products then combine with oxygen in ambient air to form the blue, outer flame, yielding carbon dioxide ( $CO_2$ ) and water ( $H_2O$ ). The neutral ratio of oxygen to acetylene is approximately 1 to 1, and the flame temperature at the tip of the inner cone is approximately 3040 °C (5500 °F). This flame is used for manual cutting.

When the oxygen-to-acetylene ratio is reduced to approximately 0.9 to 1, a bright streamer begins to appear, and the flame becomes carburizing, or reducing. A carburizing flame is sometimes used for rough cutting of cast iron. When the oxygen-to-acetylene ratio is increased to more than 1 to 1, the inner cones are shorter, "necked in" at the sides, and more sharply defined; this flame is oxidizing. Flame temperature increases until, at a ratio of approximately 1.7 to 1, the temperature is maximum, or somewhat over 3095 °C (5600 °F) at the tip of the cones. An oxidizing flame can be used for preheating at the start of the cut, and for cutting very thick sections.

According to the reaction:

an oxygen-to-acetylene ratio of 2.5 to 1 is required for a complete reaction. Of the 2.5 parts of oxygen needed for acetylene to burn completely, approximately 1.5 parts come from the air and 1 part from line oxygen. Total consumption of the line oxygen is relatively low, an advantage of acetylene over all other fuel gases. Operation of any oxyfuel equipment in confined spaces, such as the inside of a closed tank or vessel, requires strict safety considerations. Normally forced ventilation (both into and out of the enclosed space) to supply the additional air needed for both breathing and for flame combustion is provided.

Combustion occurs in stages. In the small inner cone at the tip of the torch, acetylene burns with feed-line oxygen. This reaction gives off a blistering amount of heat; the tip of the inner cone is the hottest part. Combustion starts in the inner cone and is brought to completion in a cooler, blue, outer flame. The sharp distinction between the two flames helps the cutting operator to adjust the ratio of oxygen to acetylene.

A neutral flame, recommended for manual cutting, consumes equal volumes of line oxygen and acetylene. In practice, operators may raise the line oxygen ratio to 1.5, a proportion that produces an oxidizing flame. The inner cone contracts and becomes sharply defined. This is the hottest flame attainable with acetylene or with any other raw fuel gas. The triple bond in acetylene makes it the hottest burning gas. In cutting of steel, operators should adjust the

acetylene-to-oxygen ratio to produce a neutral flame, even though it is below the highest possible temperature. A neutral flame minimizes oxidation and carburization of the base metal. Users sometimes use the hotter oxidizing flame for piercing at the start of a cut.

Acetylene is unstable at room temperature and moderate pressure and can explode under a blow even without the presence of air or oxygen. For safe storage and handling, it is dissolved in acetone. A typical cylinder is filled with heavy porous clay, which holds the acetone. Acetylene, forced into the cylinder, saturates the acetone. When the cylinder valve opens, acetylene vaporizes above the acetone solution. The regulator limits outlet pressure to 105 kPa gage pressure (15 psig) or less.

Acetylene must be used at pressures below 105 kPa (15 psi), which is a stable operating range. Safety codes specify equipment and handling practices for acetylene. When supplied in special cylinders, acetylene is dissolved in acetone, which is contained in a porous mass that fills the cylinder. This technique eliminates the sensitivity of acetylene at pressures over 105 kPa (15 psi). Such cylinders can be filled to pressures exceeding 105 kPa (15 psi) but not greater than 1725 kPa (250 psi). Acetylene may also be supplied from generators. With either means of supply, strict safety regulations must be observed to avoid sudden decomposition and explosion.

Cylinders for acetylene should be handled with care. Safety requires them to be placed upright to prevent acetone solvent from entering the regulator. The ratio of line oxygen consumption to acetylene consumption is lower than that for the other fuel gases. Acetylene uses less oxygen at its maximum flame temperature, so that handling of oxygen cylinders may be reduced, thus offsetting the inconvenience of the acetylene cylinder.

Cost of acetylene as a fuel gas changes with consumption. Large-volume users of acetylene often install bulk trailers that hook up to manifold piping systems. When volume justifies, users may install acetylene-generating plants, thus reducing handling costs.

Heat content of acetylene ( $kJ/m^3$ , or  $Btu/ft^3$ ) is lower than all gases except natural gas. Although acetylene burns at a high temperature, it has to burn at higher flow rates than other gases to deliver the same amount of heat. Acetylene releases heat rapidly in a small, concentrated area. Acetylene is a poor choice for cutting a large block of metal, because of high fuel cost and the need for large volumes of the fuel to obtain required total heat. To concentrate heat on a limited area, as in cutting thin plate, acetylene is a good choice. It burns faster than other gases, and it burns close to the torch tip. Heat energy concentrates at the tip of the tiny cone.

Acetylene gives a narrow heat-affected zone (HAZ) and possibly less distortion (depending on the volume and shape of the work) than a wider-spreading heat. It is particularly well suited to fast cutting of plate under 13 mm

(1/2 in.) thick. The hot flame cuts through heavy mill scale or rust and can make a bevel quickly with good edge quality. Acetylene facilitates short, stop-and-start cutting jobs, such as cutting structural members and reinforcing bars, because of its short preheat time. For stack cutting and for cutting heavy sections—operations requiring large heat input into a deep kerf—acetylene does not perform as well as other gases. This type of work calls for a fuel gas with high heat output in the secondary flame, such as propane or methylacetylene-propadiene-stabilized gas.

However, manual cutting is cooler with acetylene than with other gases; less heat rises into the operator's face. It is one of the most versatile and convenient fuels for shops that perform a wide range of fuel gas operations and for shops that cannot justify handling more than one gas. Data for both machine and manual oxyacetylene cutting of carbon steel plate of varying thickness are given in Tables 1 and 2.

**Natural gas** is a mixture of gases, depending on the composition at the well. One source defines the most widely used mixture as 85% methane (CH<sub>4</sub>), 4% ethane (C<sub>2</sub>H<sub>6</sub>), and 11% other (N<sub>2</sub>, H<sub>2</sub>, O<sub>2</sub>, H<sub>2</sub>O). Some wells produce natural gas with large proportions of ethane and propane. However, the main component is methane (CH<sub>4</sub>) and is therefore usually given the chemical symbol for methane (CH<sub>4</sub>).

The chemical reaction for complete combustion is:

This indicates an oxygen-to-methane ratio of 2 to 1; this ratio is used for the preheat flame. Maximum flame temperature at the tip of the inner cones is approximately 2760 °C (5000 °F). Both higher and lower temperatures have been reported; also, the optimal oxygen-to-gas ratio is approximately 2 to 1.

Although available in pressurized cylinders, natural gas usually is supplied through low-pressure lines from a local utility. Torchmakers overcome low line pressure through torch design. A siphon stream in the mixing chamber pulls the gas in at the required rate for complete combustion. Torches operate at pressures as low as 2 kPa (4 ozf/in.<sup>2</sup>) gage line pressure.

A natural gas flame is more diffuse than an acetylene flame; heat intensity is lower; and adjustment for carburizing, neutral, and oxidizing flame is less clearly defined. Initial cutting speeds are slower, and oxygen consumption is greater. Also, more time is required for preheating with natural gas than with acetylene. An excess of oxygen shortens preheat time but increases consumption of oxygen. Neither acetylene nor natural gas accumulates in low pockets. When burned alone in air, the flame of natural gas does not produce soot, as is the case with acetylene.

(a) Values do not necessarily vary in exact proportion to plate thickness, because straight-line relations do not exist among pressure, speed, and orifice sizes. (b) Lowest speeds and highest gas consumptions are for inexperienced operators, short cuts, dirty or nonuniform material. Highest speeds and lowest gas consumptions are for experienced operators, long cuts, clean and uniform material. (c) Pressure of acetylene for the preheating flames is more a function of torch design than of the thickness of the part being cut. For acetylene pressure data, see charts from manufacturers of apparatus.

(a) Values do not necessarily vary in exact proportion in plate thickness, because straight-line relations do not exist among pressure, speed, and orifice sizes. (b) Lowest speeds and highest gas consumptions are for inexperienced operators, short cuts, dirty or nonuniform material. Highest speeds and lowest gas consumptions are for experienced operators, long cuts, clean and uniform material. (c) Pressure of acetylene for the preheating flames is more a function of torch design than of the thickness of the part being cut. For acetylene pressure data, see charts from manufacturers of apparatus.

Because heat content is low and heat emission is diffuse, natural gas cannot be used to weld steel. Consequently, extra installations are needed if oxyfuel gas welding is to be performed in addition to cutting. Despite these disadvantages, use of natural gas for cutting has increased. It is the lowest-cost commercial fuel gas and, with careful torch adjustment, produces excellent cuts in light- to heavy-gage material. Data for manual oxynatural gas straight-line cutting of carbon steel plate of varying thickness are given in Table 3. Table 4 gives data for oxynatural gas shape cutting of carbon steel plate. Table 5 gives

data for machine oxynatural gas drop cutting of shapes from thick carbon steel plate.

**Propane** ( $C_3H_8$ ) is a petroleum-based fuel usually supplied as a liquid in storage tanks from which it is drawn off as a gas. The gas is dispensed from bulk storage tanks through pipelines. It has a narrow range of flammability and is relatively stable. However, propane is heavier than air and can therefore collect in low-lying areas, resulting in a fire or explosion hazard. Complete combustion requires an oxygen-to-propane ratio of 5 to 1. However, approximately 30% of the oxygen needed is taken from

the ambient air. When the ratio of oxygen to propane is 4.5 to 1, the flame temperature is approximately 2760 °C (5000 °F) at the tip of the inner cones. At 4.25 to 1, the flame temperature is approximately 2650 °C (4800 °F). Flame properties are similar to those of natural gas, with respect to diffuseness, heat intensity, flame adjustment, and cutting speed. When burned alone in air, the flame is soot-free.

**Propylene** is a liquefied gas similar to propane. It has a higher flame temperature than propane. The flame temperature of propylene is approximately equal to that of methylacetylene-propadiene-stabilized (MPS) gas, although its heat content is slightly less. However, propylene is also heavier than air and can therefore collect in low-lying areas, resulting in a fire or explosion hazard. On a volume basis, propylene is usually less expensive than acetylene; it does, however, consume more oxygen during combustion. The combustion reaction for propylene is:

The combustion ratio for propylene is 4.5 to 1. Line oxygen for a neutral flame is approximately 3.5 to 1. Distributors sell propylene under various trade names, either pure or as improved mixtures with propane and other hydrocarbon additives.

**Methylacetylene-Propadiene-Stabilized Gas.** The common trade name of MPS gas is MAPP gas. Methylacetylene-propadiene-stabilized mixtures are by-products of the manufacture of chemicals such as ethylene. These mixtures combine the qualities of an acetylene flame with a more even heat distribution in a fuel that is less prone to explosion and less costly than acetylene. It is

(a) Two-piece tips for high-speed machine cutting. (b) Variations in cutting speed may be caused by mill scale on plate, variation in oxygen purity, flame adjustment, condition of equipment, impurities in steel, and variation in heat content of natural gas.

supplied as a liquid, in large tanks or in portable cylinders.

Methylacetylene-propadiene-stabilized gases contain a mixture of several hydrocarbons, including propadiene (allene), propane, butane, butadiene, and methylacetylene. Methylacetylene, like acetylene, is a high-energy triple-bond compound. It is unstable, but other compounds in the mixture dilute it sufficiently to enable safe handling.

Compositions of MPS mixtures are proprietary and may vary; consequently, an exact combustion equation cannot be specified. The mixture burns hotter than propane or propylene. It also affords a high release of heat energy in the primary flame cone, characteristic of acetylene. The outer flame gives relatively high heat release, similar to propane and propylene. The overall heat distribution in the flame is the most even of any of the other gases. The inner cone releases 19.3 MJ/m<sup>3</sup> (517 Btu/ft<sup>3</sup>), and the outer flame releases 70.37 MJ/m<sup>3</sup> (1889 Btu/ft<sup>3</sup>). The coupling distance is therefore less exacting than for acetylene. The best coupling distance for MPS fuel places the outer cone on the plate; however, a shorter coupling distance also delivers considerable heat.

The neutral MPS gas-oxygen flame generates 89.62 MJ/m<sup>3</sup> (2406 Btu/ft<sup>3</sup>) with a 2925 °C (5300 °F) flame with a ratio of 3.5 to 4 parts oxygen to 1 part fuel. Values vary with the composition of the gas. The carburizing flame, 2.2 parts or less oxygen to 1 part fuel, can weld alloys, such as aluminum, that oxidize readily. A neutral flame, with a ratio of 2.3 parts line oxygen to 1 part fuel gas, can weld steel. At 2.8 line oxygen ratio, the flame becomes oxidizing, unsuitable for welding. Methylacetylene-propadiene-stabilized gas produces its hottest flame at 3.3 line oxygen-to-gas ratio.

In comparing the cost of MPS gas with the cost of acetylene, differences in cylinder yield and consumption rate must be considered. A 54 kg (120 lb) cylinder of MPS gas yields 17.5 m<sup>3</sup> (620 ft<sup>3</sup>) of gas; a 115 kg (240 lb) cylinder of acetylene yields only 7.4 m<sup>3</sup> (260 ft<sup>3</sup>) of gas. In addition, acetylene burns faster. Thus, storage, transportation, and time and labor for changing cylinders become important cost factors.

Methylacetylene-propadiene-stabilized gas competes with acetylene for almost every job that uses fuel gas. Its most unusual use perhaps is in deep-water cutting. Because acetylene outlet pressure is limited to 105 kPa gage pressure (15 psig), it cannot be used below 9 m (30 ft) of water. The Navy and several shipyards use MPS gas for underwater work. Table 6 provides data for oxy/MPS gas cutting of carbon steel plate.

## Effect of Oxyfuel Cutting on Base Metal

During cutting of steel, the temperature of a narrow zone adjacent to the cut face is raised considerably above the transformation range. As the cut progresses, the steel cools back through this range. Cooling rate depends on the heat conductivity, on the mass of the surrounding material, on loss of heat by radiation and convection, and on speed of cutting. When steel is at room temperature, the rate of cooling at the cut is sufficient to produce a quenching effect on the cut edges, particularly in heavier cuts in large masses of cold metal. Depending on the amount of carbon and alloying elements present (i.e., the carbon equivalent), and on the rate of cooling, pearlitic steel transforms into microstructures ranging from acicular or spheroidized carbides in ferrite to the much harder bainitic or martensitic constituents. The HAZ may be 0.8 to 6.4 mm ( $\frac{1}{32}$  to  $\frac{1}{4}$  in.) deep for steels 9.5 to 150 mm ( $\frac{3}{8}$  to 6 in.) thick. Approximate depths of the HAZ in oxyfuel gas cut carbon steels are given in Table 7. Some increase in hardness usually occurs at the outer margin of the HAZ of nearly all steels.

## Carbon and Low-Alloy Steels

**Low-Carbon Steel.** For steels containing 0.25% C or less cut at room temperature, the hardening effect usually is negligible, although at the upper carbon limit it may be significant if subsequent machining is required. Short of preheating or annealing the workpiece, hardening may be lessened by ensuring that (1) the cutting flame is neutral to slightly oxidizing, (2) the

flame is burning cleanly, and (3) the inner cones of the flame are at the correct height. By increasing the machining allowance slightly, the first cut usually can be made deep enough to penetrate below the hardened zone in most steels. Mechanical properties of low-carbon steels generally are not adversely affected by OFC. Typical data for OFC of low-carbon steel plate are given in Tables 1 through 6.

**Medium-Carbon Steels.** Steels having carbon contents of 0.25 to 0.45% are affected only slightly by hardening caused by OFC. Up to 0.30% C, steels with very low alloy content show some hardening of the cut edges but generally not enough to cause cracking. Over 0.35% C, preheating to 260 to 315 °C (500 to 600 °F) is needed to avoid cracking. All medium-carbon steels should be preheated if the gas cut edges are to be machined and may require additional postheating as well.

**High-Carbon and Alloy Steels.** Oxyfuel gas cutting of steels containing over 0.45% C and of hardenable alloy steels at room temperature may produce a thin layer of hard, brittle material on the cut surface that may crack from the stress of cooling. Preheating and annealing may alleviate hardening and the formation of residual stress.

Preheating to 260 to 315 °C (500 to 600 °F) is sufficient for high-carbon steels; alloy steels may require preheating as high as 540 °C (1000 °F). Preheat temperature should be maintained during cutting. Thick preheated sections should be cut as soon as possible after the piece has been withdrawn from the furnace.

**Postheating and annealing** also controls the effects of gas cutting in carbon and low-alloy steels. Postheating can reduce the hardness and strength level of any bainitic or martensitic microstructures formed during the cutting process as well as relieve locked-in residual stresses. Postheating immediately after oxyfuel cutting can also reduce the tendency for cracking, especially for cast irons and for alloy steels with medium-to-high carbon content. Annealing restores the original structure of the steel, whether it be predominantly pearlitic or predominantly ferritic with spheroidized carbide, and it also provides stress relief. Many steels do not require annealing if they have been properly preheated or preheated and postheated. (See *Heat Treating*, Volume 4 of *ASM Handbook*, 1991, for annealing practices for specific steels.)

**Local annealing** is a localized postheat treatment that can be used to prevent hardening or to soften an already hardened cut surface. Either the preheating flame of the cutting torch or a special oxyfuel heating torch may be used for local annealing, as well as electrical resistance heating elements and quartz lamps, depending on the mass of the workpiece and the area to be covered. The heat-affected portion of the workpiece should be heated uniformly, and the temperature gradient at the boundary of the heated mass should be gradual enough to avoid distortion of the workpiece.

Local annealing is not a substitute for preheating; it cannot correct damage done

Note: All recommendations are for straight-line cutting with a three-hose torch perpendicular to work. (a) All tips are of design recommended by the supplier. (b) Pressure of cutting oxygen measured at the torch

during cutting, such as upsetting of the metal or cracking at the cut edges. Local annealing is limited to steel plate up to 40 mm (1.5 in.) thick. From 40 to 75 mm (1.5 to 3 in.) thick, heat should be applied to both sides of the plate. This method is not suitable for thicknesses over 75 mm (3 in.). If local annealing cannot be done simultaneously with cutting, the cut edges should be tempered after cutting with a suitable heating torch.

**Local preheating** heats the volume of the workpiece enclosing the HAZ of the cut. If

**Table 7 Approximate depths of heat-affected zone (HAZ) in oxygen-cut carbon steels**

Plate thickness		HAZ depth	
mm	in.	mm	in.
<b>Low-carbon steels</b>			
< 13	< 1/2	< 0.8	< 1/32
13	1/2	0.8	1/32
150	6	3.2	1/8
<b>High-carbon steels</b>			
< 13	< 1/2	< 0.8	< 1/32
13	1/2	0.8–1.6	1/32–1/16
150	6	3.2–6.4	1/8–1/4

Note: The depth of the fully hardened zone is considerably less than the depth of the HAZ. For most applications of gas cutting, the affected metal does not have to be removed

the volume of material to be heated is small, the flame of a cutting torch can be used for preheating. When the workpiece is thick and broad, a special heating torch may be necessary. Workpieces must be heated uniformly through the section to be cut, without excessive temperature gradient.

**Distortion**, which is the result of heating by the gas flame, can cause considerable damage during (1) cutting of thin plate (less than 7.9 mm, or 5/16 in., thick), (2) cutting of long narrow widths, (3) close-tolerance profile cutting, and (4) cutting of plates that contain high residual stresses. The heat may release some of the restraint to locked-in stress or may add new stress. In either case, deformation (warpage) may occur, thus causing inaccurate finished cuts. Plates in the annealed condition have little or no residual stress.

Preheating the workpiece can reduce distortion by reducing differential expansion, thereby decreasing stress gradients. Careful planning of the cutting sequence also may help. For example, when trimming opposite sides of a plate, both sides should be cut in the same direction at the same time. When cutting rings, the inside diameter should be cut first; the remaining plate restrains the material for the outside-diameter cut. In general, the larger portion of material should be used to retain a shape for as long as possible; the cutting sequence should be

balanced to maintain even heat input and resultant residual stresses about the neutral axis of plate or part.

**Deformation.** In cuts made from large plates, the cutting thermal cycle changes the shape of narrow sections and leaves residual stress in the large section (Fig. 2). The

**Fig. 2** Effects of oxyfuel gas cutting thermal cycle on shape of sections. (a) Plate with large restraint on one side of kerf, little restraint on the other side. Phantom lines indicate direction of residual stress that would cause deformation except for restraint. (b) Plate with little restraint on either side

temperature gradient near the cut is steep, ranging from melting point at the cut to room temperature a short distance from it. Plate does not return to its original shape unless the entire plate is uniformly heated and cooled.

As the metal heats, it expands, and its yield strength decreases; the weakened heated material is compressed by the surrounding cooler, stronger metal. The hotter metal continues to expand elastically in all directions until its compressive yield strength is reached, at which point it yields plastically in directions not under restraint. The portion of this upset metal above 870 °C (1600 °F) is virtually stress-free; the remainder is under compressive stress that is equal to its yield strength. Metal that expands but does not upset is under compressive strength below yield. The net stress on the heated side of the neutral axis causes bowing of a narrow plate during cutting, as shown in Fig. 2.

As the heated metal begins to cool, it contracts, and its strength increases. First, the contraction reduces the compressive stress in the still-expanded metal. When the compressive stress reaches zero and the plate regains its original shape, previously upset metal also has regained strength. This metal is now in tension as it cools, and its tensile yield strength increases. Tension increases until the metal reaches room temperature. Residual tensile stress in the cooling side of the neutral axis causes the bowing of narrow plates after cooling (Fig. 2). Controlled upsetting is the basis of flame straightening.

## Stainless Steels

Stainless steels do not support oxyfuel combustion and therefore require metal powder cutting, flux cutting, or plasma are cutting processes. Except for stabilized types, stainless steels degrade under the heat of metal powder or flux cutting processes. Carbide precipitation occurs in the HAZ approximately 3 mm ( $\frac{1}{8}$  in.) from the edge, where the metal has been heated to 425 to 870 °C (800 to 1600 °F) long enough for dissolved carbon to migrate to the grain boundaries and combine with the chromium to form chromium carbide. The chromium-poor (sensitized) regions near grain boundaries are subject to corrosion in service. This type of corrosion can be prevented by a high-temperature stabilizing anneal after cutting, which puts the carbon back into solution. However, the required quench through the sensitizing temperature range may distort the material.

Water quenching of the cut edge directly behind the cutting torch may also avert sensitization. Because it takes approximately 2 min at sensitizing temperature for carbide precipitation to occur, water quenching must be done immediately. Distortion is more likely with this method than with the stabilizing anneal. Still another procedure is to remove the sensitizing zone entirely by chipping, grinding, or machining.

## Cast Irons

Because of high carbon content, cast iron resists ordinary gas cutting. Gray iron contains some carbon in the form of flakes of graphite and some in the form of iron carbide, both of which hinder oxidation of the iron. For this reason, gray iron is classed as oxidation-resistant with respect to gas cutting. High-quality production cuts typical of steel are not expected; iron castings usually are gas cut to remove gates, risers, and defects; to repair or alter castings in service; or for scrap.

**Techniques.** Cutting is done manually, using more preheat and cutting oxygen than is used in cutting equal thicknesses of steel. The increased gas flow is obtained by using a larger tip. The preheat flames are adjusted to be carburizing, with the excess acetylene streamer approximately equal to the thickness being cut, as shown in Fig. 3. This adjustment helps to maintain preheat in the cut, because the excess acetylene combines with cutting oxygen beyond the tip. (The same principle is used to some extent in cutting thick steel sections.)

Before the cut is started, the area of the initial cut is preheated, the point of starting is heated to melting, and then the cutting oxygen is released.

In cutting, the torch is advanced in half-circles, as shown in Fig. 4. The size of the half-circles and the speed of advance depend on the thickness of the cut. This oscillating technique helps the cutting jet to get behind and blow out the slag and molten metal at the cut. The kerf is wider and the cut edges are considerably rougher than in cutting steel. Also, oxygen and acetylene consumptions are greater.

**Other methods** for cutting cast iron, more effective than ordinary gas cutting, are metal powder cutting and flux cutting. These methods are frequently used in foundries for removing gates, risers, and sprues or for breaking up ladle skulls.

## Equipment

Commercial gases usually are stored in high-pressure cylinders. Natural gas—primarily methane—is supplied by pipeline from gas wells. The user taps into local gas lines. Acetylene, dissolved in acetone, is available in clay-filled cylinders. High-volume users often have

Fig. 3 Flame adjustments for cutting steel and cast iron

acetylene generators on site. For heavy consumption or where many welding and cutting stations use fuel gas, banks of gas cylinders are maintained at a central location in the plant, and the gas is manifolded and piped to the point of use.

Manual gas cutting equipment consists of gas regulators, gas hoses, cutting torches, cutting tips, and multipurpose wrenches. Auxiliary equipment may include a hand truck, tip cleaners, torch ignitors, and protective goggles. Machine cutting equipment varies from simple rail-mounted "bug" carriages to large bridge-mounted torches that are driven by computer-directed drives.

Gas regulators reduce gas pressure and moderate gas flow rate between the source of gas and its entry into the cutting torch to deliver gas to the cutting apparatus at the required operating pressure. Gas enters the regulating device at a wide range of pressures. Gas flows through the regulator and is delivered to the hose-torch-tip system at the operating pressure, which is preset by manual adjustment at the regulator and at the torch. When pressure at the regulator drops below the preset pressure, regulator valves open to restore pressure to the required level. During cutting, the regulator maintains pressure within a narrow range of the pressure setting.

Regulators should be selected for use with specific types of gas and for specific pressure ranges. Portable oxyacetylene equipment requires an oxygen regulator on the oxygen cylinder and an acetylene regulator on the acetylene cylinder, which are not interchangeable.

**High-low regulators** conserve preheat oxygen when natural gas or liquefied petroleum gas (LPG) is the preheat fuel used in OFC. These gases require a longer time to start a cut than acetylene or MPS. High-low regulators reduce preheat flow to a predetermined level when the flow of cutting oxygen is initiated. When the regulator switches from high to low, preheat cutback may range from 75 to 25% as plate thicknesses increase from 9.5 to 205 mm ( $\frac{3}{8}$  to 8 in.). High-low regulators are used for manual and automatic cutting with natural gas and with LPG.

**Hose.** Flexible hose, usually 3.2 to 13 mm ( $\frac{1}{8}$  to  $\frac{1}{2}$  in.) in diameter, rated at 1.4 MPa gage pressure (200 psig) maximum, carries gas from the regulator to the cutting torch. Oxygen hoses are green; the fittings have right-hand threads. Fuel gas hoses are red; the fittings have left-hand threads and a groove cut around the fittings. For heavy cutting, two oxygen hoses may be necessary—one for preheat and one for cutting

Fig. 4 Movement of torch when cutting cast iron. (a) Cutting thin cast iron. (b) Cutting heavy cast iron

oxygen. Multitorch cutting machines often have three-hose torches.

**Cutting torches**, such as the one shown in Fig. 5, control the mixture and flow of preheat oxygen and fuel gas and the flow of cutting oxygen. The cutting torch discharges these gases through a cutting tip at the proper velocity and flow rate. Pressure of the gases at the torch inlets, as well as size and design of the cutting tip, limits these functions, which are operator controlled.

Oxygen inlet control valves and fuel gas inlet control valves permit operator adjustment of gas flow. Fuel gas flows through a duct and mixes with the preheat oxygen; the mixed gases then flow to the preheating flame orifices in the cutting tip. The oxygen flow is divided—a portion of the flow mixes with the fuel gas, and the remainder flows through the cutting-oxygen orifice in the cutting tip. A lever-actuated valve on the manual torch starts the flow of cutting oxygen; machine cutting starts the oxygen from a panel control.

Fuel gases supplied at low pressure, such as natural gas tapped from a city line, require an injector-mixer (Fig. 5b) to increase fuel gas flow above normal operating pressures. Optimal torch performance relies on proper matching of the mixer to the available fuel gas pressure. The use of reverse-flow check valves on both the fuel and oxygen gas inlets of the cutting torch is an excellent safety precaution. These check valves reduce the possibility of mixing gases in the hoses and regulators. Many of these check valves are also supplied by flashback arrestors. A flashback is the burning of the preheat flame in or behind the torch mixing chamber (i.e., a shrill hissing sound when the flame is burning inside the welding torch). Flashback is usually caused

by an overheated cutting tip or by the failure to purge the gas hose lines before lighting the torch. This is a serious condition requiring immediate action. The oxygen valve should be turned off first, followed by turning off the fuel valve on the torch.

**Cutting tips** are precision-machined nozzles, produced in a range of sizes and types. Figure 6(a) shows a single-piece acetylene cutting tip. A two-piece tip used for natural gas (methane) or LPG is shown in Fig. 6(b). A tip nut holds the tip in the torch. For a given type of cutting tip, the diameters of the central hole, the cutting-oxygen orifice, and the preheat ports increase with the thickness of the metal to be cut. Cutting tip selection should match the fuel gas: hole diameters must be balanced to ensure an adequate preheat-to-cutting-oxygen ratio. Preheat gas flows through ports that surround the cutting-oxygen orifice. Smoothness of bore and accuracy of size and shape of the oxygen orifice are important to efficiency. Worn, dirty bores reduce cut quality by causing turbulence in the cutting-oxygen stream.

The size of the cutting tip orifice determines the rate of flow and velocity of the preheat gases and cutting oxygen. Flow to the cutting tip can be varied by adjustment at the torch inlet valve or at the regulator, or both.

Increasing cutting-oxygen flow solely by increasing the oxygen pressure results in turbulence and reduces cutting efficiency. Turbulence in the cutting oxygen causes wide kerfs, slows cutting, increases oxygen consumption, and lowers quality of cut. Consequently, larger cutting tips are required for making heavier cuts.

Standard tips, as shown in Fig. 7(a), have a straight-bore oxygen port. Oxygen pressures

range from 205 to 415 kPa (30 to 60 psi) and are used for manual cutting. High-speed tips, or divergent cutting tips (Fig. 7b), use a converging, diverging orifice to achieve high gas velocities. The oxygen orifice flares outward. High-speed tips operate at cutting-oxygen pressures of approximately 690 kPa (100 psi) and provide cutting jets of supersonic velocity. These tips are precision made and are more costly than straight-drilled tips, but they produce superior results—improved edge quality and cutting speeds 20% higher than standard tips. Best suited to machine cutting, high-speed tips produce superior cuts in

**Fig. 6** Types of cutting tips. (a) Single-piece acetylene cutting tip. (b) Two-piece tip for natural gas or liquefied petroleum gas. Fuel gas and preheat oxygen mix in tip. Recessed bore helps promote laminar flow of gas.

**Fig. 5** Typical manual cutting torch in which preheat gases are mixed before entering torch head. (a) Schematic view of torch. (b) and (c) Sections through preheat gas duct showing two types of mixers commonly used with the torch shown. After the workpiece is sufficiently preheated, the operator depresses the lever to start the flow of cutting oxygen. Valves control the flow of oxygen and fuel gas to achieve required flow and mixture at the cutting tip.

**Fig. 7** Oxyfuel cutting tips. (a) Standard cutting tip with straight-bore oxygen orifice. (b) High-speed cutting tip with divergent-bore oxygen orifice

plate up to approximately 150 mm (6 in.) thick. Above this thickness, advantages of their use decrease; they are not recommended for cutting metal more than 255 mm (10 in.) thick.

**Equipment Selection Factors.** Natural gas and LPGs operate most efficiently with high-low gas regulators, injector-type cutting torches, and two-piece, divergent, recessed cutting tips. Acetylene cutting is most efficient with divergent single-piece tips. If acetylene is supplied by low-pressure generators, an injector-type torch is best suited to most cutting applications.

Two-piece, divergent cutting tips are best suited for use with MPS gas; the tip recess should be less than for use of natural gas or propane. Injector-type torches and high-low regulators are not required with MPS gas.

**Guidance Equipment.** In freehand cutting, the operator can usually follow a layout accurately at low speeds, but the cut edges may be ragged. For accurate manual cutting at speeds over 250 mm/min (10 in./min), the torch tip should be guided with a metal straightedge or template. Circles and arcs are cut smoothly with the aid of a radius bar, a light rod clamped and adjusted to the torch at one end, while the other end is held at the circle center.

Machine guidance equipment includes magnetic tracing of a metal template, manual spindle tracing, optical tracing of a line drawing, guidance by numerically controlled tape or by programmable controllers, and computer-programmed guidance equipment (Fig. 8).

**Portable cutting machines** are used primarily for straight-line and circular cutting. Components include a torch mounted on a portable motor-driven carriage that travels on a

track or some other torch guidance device. The operator adjusts travel speed and monitors the operation.

Machine cutting torches are of heavy in-line tubular construction. The outer barrel of the torch has a rack, which fits into a gear on the torch holder, for raising and lowering the torch over the work. Gas ducts and valves are encased in the cutting torch barrel. The cutting tip is mounted in line with the outer barrel axis. A valve knob or a lever-operated poppet valve replaces the spring-loaded cutting-oxygen lever of the manual cutting torch that would require continued hand pressure.

On some portable machines, gases are supplied to connections on the carriage, rather than directly to the torch to avoid hose drag on the torch. Short hoses are used from machine connections to the torch. Some carriages can accommodate two or more torches operating simultaneously, for such operations as squaring and weld joint beveling.

The operator follows the carriage to make adjustments. When plates are wavy or distorted, the operator may need to adjust torch height to avoid losing the cut. When carefully operated, track-guided torches can produce cuts at speeds and quality approaching those obtainable with large computer-controlled stationary cutting machines.

**Stationary cutting machines**, as shown in Fig. 8 and 9, are used for straight-line and circular cuts, but their primary use is for cutting complex parts, that is, for cutting shapes. Plate to be cut is moved to the machine. The plate is positioned on a large table, where the plate is supported at a large number of points with very

little surface area of the supports exposed to the cutting action. Some of these tables are filled with water to help reduce the fume generation from the cutting operation. Sometimes, the cutting table is equipped with a down-draft exhaust system to remove the fume from the cutting area.

On shape-cutting machines, cutting torches move left and right on a bridge mounted over the cutting table. The bridge moves back and forth on supports that ride on floor-mounted tracks. The combined movement of the torches on the bridge and the bridge on the track allows the torch to cut any shape in the  $x$ - $y$  plane. Bridges are either of cantilever or gantry design. Suppliers classify cutting-machine capacity by the maximum width of plate that can be cut.

**Machine Directions.** Methods for directing the motion of shape-cutting machines have become increasingly sophisticated and include manual, magnetic, and electronic means of control. The simplest machines have one or two torches and use manual or magnetic tracing.

For manual tracing, the operator either steers an idler wheel or spindle around a template or guides a wheel or focused light beam around an outline on paper. Cutting speed is controlled by setting the speed of the tracing head (pantograph director) or by setting the speed of the torch carriage (coordinate drive). Cutting speed in manual tracing is approximately 350 mm/min (14 in./min), depending on operator skill.

Magnetic tracing is done with a knurled magnetized spindle that rotates against the edge of a steel template. The spindle is linked to a pantograph. Direct-reading tachometers, showing cutting speed in inches per minute, assist in

(a)

(b)

(b) Closeup of CNC control console. Courtesy of ESAB North America, Inc.

adjusting cutting speed. These control methods are relatively slow.

Faster, electronic tracers use a photoelectric cell that scans the reflection of a beam of light directed on the outline of a template. Templates are line drawings on paper, white-on-black paper cutouts, or photonegatives of a part outline. To hold tolerances closer than 1.6 mm ( $1/16$  in.) continuously, templates of plastic film, glass cloth, or some other durable, dimensionally stable material should be used.

In scanning the edge of a white-on-black template, the circuit through the photoelectric cell balances when the cell senses an equal amount of black and white. A change in this balance sends an impulse to a motor that moves the tracing head back to balance. In line tracing, the photoelectric cell scans the line from side to side. As long as the light reflects equally from both sides of the line, the steering signals balance. When the photocell scans more light on one side of the line than on the other, the scanner rotates to balance.

Some machines adjust to permit parts to be cut approximately 0.8 mm ( $1/32$  in.) larger or smaller than the template. This feature, called kerf compensation, is useful for cutting to close tolerances, especially when the template has insufficient kerf allowance.

Coordinate-drive machines translate motion 1 to 1 or in other ratios. Such ratio cutting permits the use of templates in any proportion, from full-scale to one-tenth of part size.

**Tape Control.** Cutting-machine movement may be controlled by programmed electronic signals stored on magnetic tape (numerical control). This form of control started with the use of punched tapes, similar to punched computer

cards. These machines do not require templates, and the tapes may be easily stored and used many times.

Some cutting machines receive directions from a microprocessor, programmed directly or from a program stored on a tape. The most sophisticated machines take directions directly from a computer (computerized numerical control) and use computer graphics (Fig. 8).

**Nesting of Shapes.** Savings in material, labor, and gas consumption can be gained by nesting parts in the stock layout for single-torch or multiple-torch operation. Savings can be realized whenever one cut can be made instead of two. Sometimes, a shape can be modified for better nesting. The advent of computer graphics allows cutting-machine programmers to create layouts of part patterns on cathode ray tube screens, manipulating cutting patterns for greatest plate use. Several firms offer programs that optimize parts nesting.

## Starting the Cut

To start a cut at the outer edge of the workpiece, the operator should place the cutting torch so that the ends of the inner cones in the preheating flame just clear the work metal. When a spot of metal at the top of the edge is heated to bright red, the stream of cutting oxygen is turned on. The reactions form a slot in the plate edge, and the torch can move along the desired line of cut. Piercing starts are necessary to cut holes, slots, and shapes.

In manual piercing, the spot should be heated to bright red. Then, the torch should be raised to

13 mm ( $1/2$  in.) above the normal cutting distance, and cutting oxygen should be turned on slowly. As soon as the metal is penetrated, the torch is lowered to cutting height, and cutting action is started.

Machine torch piercing is similar to manual operations, except that torch travel begins after the cutting oxygen is slowly turned on and the flame starts to eject molten slag. Initial piercing action does not completely penetrate the plate, so that the completed pierce covers a short distance (depending on plate thickness) and forms a sloping trough with molten slag ejected from the torch. Length of the lead-in should be increased for heavy plate.

## Light Cutting

Light cutting (material less than 9.5 mm, or  $3/8$  in., thick) requires extra care in tip selection, tip cleanliness, and control of gas pressure. Quality of cut when oxyfuel gas cutting steel thinner than 3.2 mm ( $1/8$  in.) is virtually impossible to control. Wide, uneven kerf, ragged edge, and distortion result from heat buildup.

For straight or large-radius cuts in thicknesses 3.2 mm ( $1/8$  in.) and over, angling the cutting torch forward increases the distance through the cut and may help to deflect some of the heat input. When cutting shapes, however, the torch must be vertical.

One of the most important techniques for cutting of thin sections is stack cutting (see the section "Stack Cutting" in this article for more detailed information on this process). This technique avoids the difficulties inherent in light

Fig. 9 Stationary oxyfuel gas cutting machine

cutting and also increases production. Sections stacked for cutting must be flat and tightly clamped together.

## Medium Cutting

In cutting plate 9.5 to 255 mm ( $\frac{3}{8}$  to 10 in.) thick, OFC achieves its highest efficiency and produces the most satisfactory cuts. Conditions for medium cutting of carbon steel plate using a variety of oxyfuel combinations are presented in Tables 1 through 6. Commercial cuts must meet these requirements:

- Drag is short; markings on the face of the cut approach vertical.
- Side of the cut is smooth, not fluted, grooved, or ragged.
- Slag should not adhere to the bottom of the cut.
- Upper and lower edges should be sharp.
- Cost is moderate.

The following variables require adjustment to obtain satisfactory commercial cuts:

- Suitable cutting tip, with cutting orifice of correct type and size, and proper degree of preheat
- Suitable oxygen and fuel gas pressures
- Correct cutting speed
- Uniform torch movement
- Clean, smooth-bore cutting orifice and preheat holes
- High-purity oxygen
- Proper angle of the cutting jet in relation to the upper edge of the cut

Surface finish for gas-cut production parts is compared with sample cuts. One such group of machine-cut samples is shown in Fig. 10. Sample A represents high quality, with drag varying approximately 2 to 7%. Samples B, C, D, and E show typical defects resulting from improper cutting speed or torch settings. The American Welding Society (AWS) provides standard plastic samples of cut edges.

**Tip Design.** General-purpose cylindrical-bore tips operate best with cutting-oxygen pressures of 205 to 415 kPa (30 to 60 psi); a pressure of 275 kPa (40 psi) is a good initial setting. Divergent-orifice tips operating with cutting-oxygen pressures of approximately 690 kPa (100 psi), with variations of  $\pm 140$  kPa ( $\pm 20$  psi), may provide better results. Because tip size controls kerf width, a smaller tip should be used for a narrower kerf; the part may not drop free, and slower speed must be used. Larger-than-normal tips may be used when the metal is covered with thick scale.

**Cutting Speed.** Within recommended speed ranges, slow cutting produces the best results; higher speeds are used for maximum output. Optimal cutting speed may be determined by observing the material that is expelled from the underside of the workpiece. When speed is too slow, the cutting stream forms slag drippings. At excessive speed, a stream trails at a sharp angle

to the bottom of the workpiece. Highest-quality cutting occurs when a single, continuous stream is expelled from the underside for approximately 6.4 mm ( $\frac{1}{4}$  in.), then breaks into a uniform spray. This condition is accompanied by a sound similar to that of canvas ripping.

**Preheat.** Less preheat is needed to continue a cut than to start it. When optimal quality is desired, the amount of preheat should be reduced after starting the cut. Commercially available devices automatically reduce preheat after cutting begins.

In thicknesses up to 50 mm (2 in.), excessive preheat may cause the top corner to melt and roll over. Insufficient preheat results in loss of cut. Correct preheat provides a continuous reaction with a sharp, clean top edge of the cut.

Kerf compensation, or the allowance of half the kerf width on the outline of the template, is the amount added for outside cuts and subtracted for inside cuts. In straight-line cutting or in following a layout, the operator may compensate for this measurement; in machine cutting, kerf compensation should be incorporated in the template. Many automatic machines incorporate kerf compensation in their controllers.

**Machine Accuracy.** When a machine is properly maintained, the guidance system controls accuracy. Mechanical followers are very accurate when properly adjusted. Compensation for the diameter of the follower wheel or spindle must be made in the same manner as for kerf width when making a template.

Kerf angle, the small deviation of the kerf wall from a right angle, may be caused by failure to set the torch perpendicular to the work. It may also be the result of widening of the cutting-oxygen stream. In the latter case, the width of the kerf increases from the top to the bottom of the cut; this may be corrected in straight cutting by angling the torch slightly to make one wall of the kerf perpendicular. In shape cutting, where this cannot be done, kerf angle can be corrected by slightly reducing cutting-oxygen pressure.

Plate movement may be vertical, caused by warp, or lateral, caused by planar expansion and contraction of the part. Vertical movement requires either manual or automatic control of torch height. A very slight allowance can be made in the initial setting of the tip-to-work distance. Lateral movement can be controlled by fixing the part to be cut on the plate support, wedging the cut within the stock plate, or allowing only a small amount of scrap trim around the part so that the scrap will move instead of the workpiece.

## Heavy Cutting

Cutting of metal 255 mm (10 in.) or more in thickness requires attention to gas flow, preheat flame setting, drag, and starting technique. Standard cutting torches may be used to cut steel up to 455 to 510 mm (18 to 20 in.) thick; heavy-duty torches are necessary for sections up to 1525 mm (60 in.) thick.

**Gas Flow Requirements.** Heavy cutting requires a uniform supply of high-purity oxygen and fuel gas at constant pressure, and an adequate volume of cutting oxygen. Torches should have three hoses—one for the cutting oxygen, one for the preheat oxygen, and one for the fuel gas. This

**Torch settings for bar A(a)**

Preheat-oxygen pressure:	
High (edge starting)	310 kPa (45 psi)
Low (cutting)	55–83 kPa (8–12 psi)
Preheat natural gas pressure:	
High (edge cutting)	21 kPa (3 psi)
Low (cutting)	Under 430 Pa (1 oz/in. <sup>2</sup> )
Cutting-oxygen pressure	690 kPa (100 psi)
Cutting speed	255–380 mm/min (10–15 in./min)

(a) Settings for bars B, C, D, and E were varied as noted in the caption. All bars were cut with two-piece divergent-nozzle (high-speed) tips with 1.37 mm (0.054 in.) diam cutting-oxygen orifice. All cutting was done with low preheat settings, except for bar B, which was cut with both preheat gases set higher than for starting.

**Fig. 10** Comparison of surface finish of gas-cut specimens. (a) Proper speed, preheat, and cutting-oxygen pressure. Note clean face and nearly straight drag lines. (b) Proper speed and cutting-oxygen pressure, too much preheat. Note excessive slag and rounding of top edge. (c) Proper preheat and cutting-oxygen pressure, but too much speed. Note increase in drag and uncut corner at lower left. (d) Proper speed and preheat, but too much cutting-oxygen pressure. Surface is rough, and top edge is melted. (e) Proper preheat and cutting-oxygen pressure, but speed too low. Burned slag adheres to cut surface.

allows setting of proper pressures independently for preheating and cutting. Cutting-oxygen hose should be at least 13 mm ( $1/2$  in.) in diameter to ensure an adequate volume of oxygen at low pressure settings. Regulators should be used that are capable of providing the large volumes of gas required. Cutting-oxygen flow requirements ( $\text{ft}^3/\text{h}$ ) vary from 80 to 120 times ( $80t$  to  $120t$ ) the thickness to be cut measured in inches. Cutting-oxygen consumption for shape cutting

approaches  $120t$  or higher; for straight-line cutting, it is between  $80t$  and  $100t$ . Pressures are 140 to 415 kPa (20 to 60 psi) at the torch.

**Preheating.** In heavy cutting, the preheat flame must extend almost to the bottom of the thickness to be cut to avoid excessive drag. If the cutting torch cannot deliver enough heat, an extra torch may be needed, or the workpiece may be furnace heated. A temperature boost of 95 to 150 °C (200 to 300 °F) assists cutting action

considerably. Tip height above the work is important; if the tip is too close, excessive melting and rounding of the top edge occur. If too high, preheat will be insufficient and cutting will be slowed. Generally, 25 to 50 mm (1 to 2 in.) of separation is satisfactory.

The starting edge should be thoroughly preheated, with the preheated zone extending far down the face, as shown in Fig. 11(a). As soon as the metal begins to melt, the flow of cutting oxygen and the cutting motion should proceed simultaneously, cutting at normal speed. The cut should progress down the face at a constant rate until it breaks through the bottom. Drag will be long at first, but it will shorten as soon as the cut is confined. Too slow a speed causes a shelf part way through the cut edge (Fig. 11e). Too high a speed results in incomplete penetration or in extremely long drag, as shown in Fig. 11(f).

**Drag.** To successfully complete the cut (drop cutting), minimum drag conditions must exist, as shown in Fig. 12(a). Too much drag leaves an uncut corner at the end of the cut (Fig. 12b and c). Angled cutting may be used in straight-line work to counter drag (Fig. 12d and e), but for shape cutting, the torch must be perpendicular to the work.

**Starting.** Extra care is needed in starting a heavy cut to avoid leaving an uncut corner or pocketing the flame in the lower portion of the cut. Starting sometimes is facilitated by first undercutting the forward edge of the material with a hand torch (Fig. 13).

**Fig. 11** Proper and improper techniques for heavy cutting. (a) Proper torch position; preheat is primarily on starting face. (b) Improper start; oxygen stream is too far onto work, which results in action of cut as shown in (c) and in uncut corner as shown in (d). (e) Excessive oxygen pressure or action of cut at too low a speed. (f) Insufficient oxygen pressure or action of cut at too high a speed

**Fig. 12** Proper and improper techniques for completing a heavy cut. (a) Minimum drag (typical at balanced conditions) permits flame to break through cutting face uniformly at all points. (b) Excessive drag, typically caused by insufficient oxygen or excessive speed, results in undercut. (c) Forward drag resulting from excessive oxygen pressure or too little speed. (d) and (e) Forward angling of torch to minimize drag and thus avoid an uncut corner. (f) Excessive forward angling of torch, resulting in undercut

## Stack Cutting

Stack cutting is a practical means of cutting sheets too thin for ordinary cutting, but it also can reduce the cost of cutting thicker material. Savings are multiplied by using multitorch machines for stack cutting. Several torches can be used, each cutting up to 30 pieces of 3.2 mm ( $1/8$  in.) thick material simultaneously. Thicknesses most practical for this technique are 20 gage (0.91 mm, or 0.036 in.) to 13 mm ( $1/2$  in.), although material 19 mm ( $3/4$  in.) thick has been stack cut. Shapes made by stack cutting usually have sharper edges than those cut singly.

Material for stack cutting should be clean and free from loose or heavy scale. The sheets or plates must be clamped tightly in a pile, with edges aligned where the cut is to start. Air gaps between pieces will interfere with the cutting flame. The most practical total thickness for the stack is 125 or 150 mm (5 or 6 in.), although 250 mm (10 in.) stacks have been cut. The risk

**Fig. 13** Undercutting as an aid in starting a heavy cut

of a costly mishap increases with the thickness to be cut and the number of pieces.

When stack cutting pieces less than 4.8 mm ( $\frac{3}{16}$  in.) thick, a waster plate of 6.4 mm ( $\frac{1}{4}$  in.) material is clamped atop the stack. The waster plate ensures better starting and a sharper edge for the top. It also prevents buckling.

In addition to increasing productivity, stack cutting also reduces materials handling, grinding and cleaning costs, gas consumption, and floor-space requirements. However, savings must justify the time for stacking and clamping. The method is best used when the flat sheets are bundled in stacks at the steel mill.

An application of stack cutting, as practiced in a diesel engine plant, is described in the first example that follows.

When comparing stack cutting with multi-torch machine cutting, the deciding factor in making the choice is not the actual cutting time per piece. The saving includes reduced materials handling, less grinding and cleaning, and lower gas consumption. The second example that follows describes an application in which stack cutting required less time than multitorch cutting of small lots of a simple shape.

**Example 1: Stack Cutting of Cooling-Fan Side Plates (Fig. 14).** The cooling fan of a direct-current main generator for a diesel locomotive consisted of two side plates, 132 cm (52 in.) outside diameter by 76 cm (30 in.) inside diameter by 4.8 mm ( $\frac{3}{16}$  in.) thick, between which 24 fan blades were riveted. The assembled fan was 15.9 cm ( $6\frac{1}{4}$  in.) wide. The side plates (Fig. 14) were cut in stacks of 20 to

#### Torch settings

Cutting tip	Two-piece divergent type
Diameter of cutting-oxygen orifice	1.7 mm (0.067 in.)
Flow rates (approx):	
Natural gas preheat	0.96 m <sup>3</sup> /h (34 ft <sup>3</sup> /h)
Preheat oxygen	1.9 m <sup>3</sup> /h (68 ft <sup>3</sup> /h)
Cutting oxygen	10 m <sup>3</sup> /h (356 ft <sup>3</sup> /h)
Cutting speed (25 pieces)	150 mm/min (6 in./min)

#### Alternative production methods

Up to 10 pieces	Nibble, saw, machine turn(a)
10 to 25	Stack gas cut (portable machine)
25 to 1000	Stack gas cut (stationary machine)
Continuous production(b)	Die blank

(a) Methods listed in descending order of preference. (b) Minimum quantity, 1000 pieces per year, two years' production

**Fig. 14** Stack-cut flat ring (example 1). Dimensions in inches

30 in a two-torch gas cutting machine with an electronic tracer, using only one cutting torch. An injector-type torch with a two-piece divergent cutting tip was used with the oxynatural gas process. Torch settings and other processing details are shown in the table with Fig. 14, together with alternative production methods.

**Example 2: Stack Cutting versus Multitorch Machine Cutting (Fig. 15).** A six-torch gas cutting machine with an electronic tracer was used to cut the 46 cm (18 in.) perimeter of the 9.5 mm ( $\frac{3}{8}$  in.) thick triangle shown in Fig. 15. At a cutting speed of 48 cm/min (19 in./min), six pieces were cut in 0.95 min, or 0.158 min per piece. However, each piece required 0.5 min of light grinding to clean the edges. Total time for these two operations was 0.658 min per piece. With setup time of 2.3 min per piece added, total time per piece was 2.958 min.

When stack cutting was used, the material came from the mill in bundles of 13 plates. The plates were supplied in sizes for convenient multiples of the nested shape, the total quantity being based on estimated needs for several months. Bundles were stored as received and used as required. Each bundle of 13 plates made a stack 12.4 cm (4 $\frac{7}{8}$  in.) high.

A single torch was used for stack cutting. At a cutting speed of 18 cm/min (7 in./min), 2.571 min was required for cutting the stack, or 0.198 min per piece. This was approximately 25% longer than it took with the multitorch machine. However, only the bottom plate of each stack required light grinding, making the cleaning time per piece 0.038 min. Setup time was 1.662 min per piece. Total time per piece for all operations was therefore 1.898 min—or 36% less than by the six-torch method.

## Preparation of Weld Edges

Steel plates to be welded are resquared, trimmed to size, cut to shape, and beveled by gas cutting, often in one operation. Some cutting also is done on forgings and castings to prepare them for welding. Cutting accuracy can be held to 6 or 3 mm ( $\frac{1}{4}$  or  $\frac{1}{8}$  in.), and squareness and smoothness of the cut edges are usually satisfactory. Adherence of slag to the underside of the

**Fig. 15** Triangle that was produced in 36% less time when gas cut in stacks of 13 with a single torch than when six pieces were individually gas cut at one time with a six-torch machine (example 2). Dimensions in inches

cut can be closely controlled; however, a light cleaning operation may be needed. If so, a wide-blade chisel, a grinding wheel, or a wire brush may be used.

**Bevel cutting** differs from ordinary profile cutting in that the cut edge, instead of being square with the plate surface, is at an angle. Bevel cutting is used primarily to prepare the edges of plate for welding. Some bevels are cut to remove a sharp corner (see "Example 7: Gas Cutting versus Band Sawing" in this article) or to cut shapes.

Single and double bevel cuts usually vary from 30° to 45°, measured from the square, uncut edge. Low-quality cut surfaces may result for bevels of less than 10° unless an extra scrap allowance is made. For bevels greater than 60°, it is difficult to maintain proper preheat temperature.

Standard cutting equipment is used for cutting bevels in straight-line cutting and in cutting circles. Most shapes cannot be bevel cut by standard machines, because there is no provision for rotating the torch with a change in direction. Some tape-controlled machines have a rotating-torch mechanism for cutting beveled shapes. Circular bevel cutting can be done with portable equipment that can use a radius bar. Sometimes, the workpiece can be rotated past a stationary cutting torch.

Cutting-tip selection for beveling requires special consideration, for two reasons:

- When the cutting tip is inclined to the metal surface, heat transfer to the plate is reduced.
- Because of the angle, the actual cutting thickness is greater than the plate thickness.

**Preheating for Bevel Cutting.** Torch inclination does not affect the oxidizing action of the cutting-oxygen stream if preheat is adequate. Therefore, tip size (size of cutting-oxygen orifice) and cutting-oxygen flow are selected on the basis of the as-cut thickness. Preheat gas flow, however, is affected in two ways:

- As the angle of inclination increases, heat transfer becomes less efficient, and more preheat gas flow is required.
- In contrast to perpendicular cutting, more preheat is required for thinner materials.

(The latter effect may be related to the percentage of heat deflected and to the higher speeds at which thinner materials are cut; the effect disappears in metal thicknesses greater than 10 cm, or 4 in.)

Because preheat is important in bevel cutting, several techniques, in addition to increased preheat gas flow, are used to obtain proper preheat. The best position for oxyacetylene cutting is that in which the uppermost cones of flame touch the plate surface while the lower cones extend into the cut. A second torch may be used to precede the cutting torch, for additional preheat. Also, extra preheat tips, called bevel adapters, are available. These adapters have a special heating nozzle offset from the cutting tip so that, when

the cutting tip is inclined at 45°, the heating tip is normal to the plate, as shown in Fig. 16. Bevel adapters are right-hand or left-hand; therefore, two may be needed. Much beveling is done, however, without special equipment.

Data for bevel cutting with adapters, using natural gas preheat, are shown in Table 8. This table also can be used when cutting bevels without the use of extra preheat tips, by selecting the next larger tip to provide the extra preheat needed, due to torch inclination. For example, a 45° bevel having a 9.5 mm ( $\frac{3}{8}$  in.) A and B dimension requires a 0.93 mm (0.037 in.) orifice tip with an adapter; the same bevel without an adapter would require a 1.37 mm (0.054 in.) orifice tip and the settings listed for it. The cutting-tip height for oxynatural gas beveling should be approximately 3 to 6 mm ( $\frac{1}{8}$  to  $\frac{1}{4}$  in.) at the closest point above the work. For bevels larger than those for which dimensions are given in Table 8, the torch-to-work distance usually is increased.

When a plate must be trimmed to size as well as partly beveled, both operations can be done at the same time, using two torches close together, with the perpendicular torch leading. Special multitip bevel-cutting heads are also available for this purpose. Two torches may similarly be used for cutting a double bevel intersecting at an edge, with the leading torch cutting the underside bevel. Three torches can be used to cut a double bevel with a short vertical face between bevels; the torch cutting the underside bevel leads, the perpendicular torch follows, and the torch cutting the upper bevel is last.

Because preheat is so important in bevel cutting, and the acetylene flame has better heat transfer, oxyacetylene bevel cutting is more efficient than oxynatural gas or oxypropane bevel cutting in thicknesses up to 10 cm (4 in.). Methylacetylene-propadiene-stabilized gas has also proved advantageous for bevel cutting.

**J-Grooving.** A type of gas cutting known as J-grooving sometimes is used to prepare the edges of heavy pressure vessels for welding. The purpose is to provide a groove with less cross-sectional areas than an angular bevel would provide in a heavy plate, thus saving time, labor, and filler metal in welding. The cutting tips used in this operation are gouging tips; hence, J-grooving is discussed in the section "Oxyfuel Gouging."

**Fig. 16** Cutting a bevel with an extra preheat tip, or bevel adapter. For beveling in the opposite direction, an opposite-hand adapter is needed. Dimensions in inches

## Applicable Shapes

Irregular shapes may be cut by special techniques, or may be beyond the practical limits of gas cutting.

**Cutting of Bars and Structural Shapes.** To cut round steel bars, gas pressure should be adjusted for the maximum thickness (diameter), and the cut should be started at the outside. As the cut progresses, the torch should be raised and lowered to follow the circumference. The bar should be nicked with a chisel to make a burr at the point where the cut is to begin. Oxyfuel gas cutting of round bars is usually manual, so the cut surface is rough. The chief advantage of OFC over sawing is that the torch can be brought to the work.

The same advantage applies to gas cutting of various structural shapes, although cutting can be smoother and sharper because it can be guided on the flanges and webs. Extra care must be taken when cutting thick filleted sections. These cuts usually are satisfactory for welding but may

require light grinding if exposed to view. Columns that require end capping usually are machined to exact size.

**Circular holes** can be gas cut, rather than drilled, if the hole wall does not require a machined finish, and if the roundness and concentricity have wide tolerances. The following types of holes can be made by gas cutting: clearance holes for piping and bolting; concrete grouting holes; holes for piping where the pipe is welded to the piece containing the hole; inspection or access holes; and holes for plug welds.

Holes can best be gas cut with the aid of electronic tracers. Accuracy depends on template accuracy. Hole location and hole size in plate up to 7.6 cm (3 in.) thick can be held readily to the tolerances listed in Table 9. As shown in Table 10, the cut is advanced from a pierced starting hole. In piercing, the slag must be removed from any area that the flame will later touch. This is particularly important for small holes.

Recommended minimum hole diameters are shown in Table 10. The two levels of quality

**Table 8** Torch settings for various bevels, using extra preheat tip (bevel adapter) in oxynatural gas cutting

Note. Extra preheat tip to be set 6.4 to 9.5 mm ( $\frac{1}{4}$  to  $\frac{3}{8}$  in.) above plate surface. For proper torch setting, adjust preheat for slight whistle, then reduce oxygen slightly. (a) Two-piece tips for high-speed machine cutting. Corresponding tip sizes of different manufacturers vary in performance because of differences in construction of torches and mixers.

shown indicate the influence of hole size on accuracy. Normal production tolerances (Table 9) are difficult to maintain in thicknesses over 7.5 cm (3 in.), because of kerf angle. Holes larger than those listed can be gas cut to normal production tolerances.

**Slots.** The procedure for gas cutting of slots is the same as that for gas cutting of holes. Table 10 lists minimum slot sizes that can be cut to normal tolerances, and contains a sketch that illustrates torch movement. Slots can be made at less cost by gas cutting than by profile end milling, if a machined edge is not mandatory.

**Borderline Shapes.** The next four examples illustrate shapes that are borderline for gas cutting. The first example concerns a shape in which two sides had to be exactly perpendicular. In the second example, three sides of a shape were required to hold a tolerance of  $+0, -0.8$  mm ( $-1/32$  in.).

In the third example, a shape with a narrow pointed end was required to maintain sharp edges and corners. When gas-cut shapes have rounded top edges (rollover), the cause usually is excessive preheat. However, this condition can also occur when the cutting path surrounds too small a mass of the shape being cut, causing excessive heat accumulation, as in the application described in the example that follows.

**Table 9 Dimensional tolerances normally obtainable in production gas cutting of plate**

Plate thickness, cm (in.)	Tolerance, mm (in.)
Up to 1.3 (1/2) inclusive	$\pm 1.6 (\pm 1/16)$
Over 1.3 to 2.8 (1/2 to 1 1/8)	$\pm 2.4 (\pm 3/32)$
Over 2.8 to 7.6 (1 1/8 to 3)	$\pm 3.2 (\pm 1/8)$
Over 7.6 to 13 (3 to 5)	$\pm 4.0 (\pm 5/32)$
Over 13 to 15 (5 to 6)	$\pm 4.8 (\pm 3/16)$
Over 15 to 20 (6 to 8)	$\pm 5.6 (\pm 7/32)$
Over 20 to 25 (8 to 10) inclusive	$\pm 6.4 (\pm 1/4)$

For machine cutting with equipment in good working condition, and with adequate control for minimizing distortion in cutting shapes and long, narrow pieces.

**Table 10 Recommended minimum dimensions for machine gas-cut holes and slots**

Work metal thickness		Minimum hole diameter				Minimum slot size(b)	
		Rough cuts(a)		Accurate cuts(b)			
mm	in.	mm	in.	mm	in.	mm	in.

50-72	2-27/8	25	1	50	2	25 by 38	1 by 1 1/2
75-122	3-47/8	50	2	...	...	38 by 50	1 1/2 by 2
127-197	5-73/4	75	3	...	...	50 by 75	1 1/2 by 3

Arrows indicate direction of cutting

Note: Holes or slots are cut from pierced starts as illustrated above. Torch settings are as indicated in tables of cutting conditions for the fuel gas used. (a) Accuracy will be somewhat less than normal tolerances shown in Table 9. (b) Normal production tolerances shown in Table 9 will be maintained. Minimum sizes of holes are larger than those of slots because circular holes are more difficult to cut.

The fourth example describes a shape that contained a long slot, narrower than the minimum recommended for normal accuracy in Table 10. In this example, the narrow re-entrant cut is the opposite of a projection in Example 5. Here, it was questionable whether normal production tolerances could be maintained if the part was flame cut.

**Example 3: Two Perpendicular Sides.** The gusset shown in Fig. 17 was gas cut from 13 mm (1/2 in.) thick low-carbon steel so that sides A and B would be  $90^\circ$  to each other. By positioning the part a minimum of 50 mm (2 in.) from any edge of the plate and cutting in a clockwise direction, the restraint of the uncut portion of the plate was used to keep the two adjacent sides of the gusset in position during machine gas cutting. As shown in Fig. 17, the cut was started clockwise, from a pierced start, along the noncritical side. The shorter side A, then side B, were cut so that they could not move in relation to each other. The noncritical sides were cut last.

The cutting machine was equipped with an injector torch for use with low-pressure natural gas. A high-speed, two-piece cutting tip was used, together with high-low gas regulators. The operating procedure and torch settings used are given in the table that accompanies Fig. 17.

**Example 4: Three Close-Tolerance Sides.** Figure 18 shows the layout for gas cutting a part that had to fit a welding fixture. Two methods were used to hold the contour bounded by surfaces A, B, and C to a tolerance of  $+0, -0.8$  mm ( $-1/32$  in.):

- Wedges were inserted into the kerf, locking the shape to the plate for maximum restraint.
- The effects of distortion that remained were overcome by making allowances in the template.

The latter was accomplished by making cutting tests and measuring and adjusting the master aluminum template until the proper shape was developed. The master template was used only for preparing the template used on the job.

The equipment for cutting was the same as that described in the previous example. Operating procedure and torch settings are given in the table that accompanies Fig. 18. Although the procedure mentions the use of a paper template, a plastic template was substituted later, to extend template life to more than 4 h.

**Example 5: Shape with Narrow Pointed End.** The 19 cm (7.5 in.) thick shape shown in Fig. 19 included a narrow portion where the cutting path doubled back. Although the finished shape was within the tolerances given in Table 9, a slight rounding of the top edge of the 25 mm (1 in.) wide projection and of point A (Fig. 19) was observed. From top to bottom, the kerf width increased 1.6 mm (1/16 in.) per side, making the 25 mm (1 in.) projection 22 mm (7/8 in.) wide at the bottom with a kerf angle of approximately  $1/2^\circ$ .

To start the cut for this shape, a hole was flame pierced to the left of the centerline at the top, and from it the cut progressed as shown in the sketch. Because of the deviations described previously, this shape was considered borderline insofar as process capability was concerned, in spite of the fact that tolerances were not exceeded.

The minimum width for a projection, such as on the shape that was cut in this example (Fig. 19), is a function of plate thickness. This relation cannot be stated precisely, mainly because the rounding of corners is also a function

#### Operating procedure

1. Ink trace paper template from master template. Use magnets to hold template for tracing and cutting.
2. Locate and space items on template and plate as shown.
3. Set torch tip 13 to 19 mm (1/2 to 3/4 in.) above plate.
4. Cut in clockwise direction.
5. Inspect first piece on each plate.
6. Destroy paper template 4 h after it is made.

#### Torch settings

Preheat oxygen:	
High	235 kPa (34 psi)
Low	95 kPa (14 psi)
Preheat natural gas:	
High	7 kPa (1 psi)
Low (adjust by eye)	< 7 kPa (< 1 psi)
Cutting oxygen	485 kPa (70 psi)
Orifice diameter	1 mm (0.039 in.)
Speed	455 mm/min (18 in./min)

**Fig. 17** Gas cutting a gusset with two perpendicular sides (example 3). Dimensions in inches

of the size of the tracing follower and the diameter of the cutting flame. The following table, however, may be used as a guide:

Plate thickness		Minimum projection width	
mm	in.	mm	in.
6.4	1/4	9.5	3/8
13	1/2	13	1/2
25	1	19	3/4
38	1 1/2	25	1
51	2	32	1 1/4
76	3	38	1 1/2
76-197	3-7 1/4	51	2

The opposite of a projection is the narrow re-entrant cut described in the next example.

**Example 6: Narrow Re-entrant Cut.** The 7.6 cm (3 in.) thick shape shown in Fig. 20 was cut within  $\pm 3.2$  mm ( $\pm 1/8$  in.) (the tolerance given in Table 9), even though the 13 mm ( $1/2$  in.) wide slot was narrower than the minimum width recommended in Table 10, and the 25 mm (1 in.) projection was less than the 38 mm (1.5 in.) nominal minimum for 7.6 cm (3 in.) stock. The shape was cut by machine, using natural gas preheat fuel.

Two problems were anticipated. One was that the heat buildup in the 13 mm ( $1/2$  in.) portion of the slot would burn up the scrap, causing an irregular path for the cutting flame. The other

#### Operating procedure

1. Ink trace paper template from master template. Use magnets to hold template for tracing and cutting.
2. Set torch tip 13 to 19 mm ( $1/2$  to  $3/4$  in.) above plate.
3. Cut in clockwise direction with single torch.
4. Wedge approximately 13 mm ( $1/2$  in.) behind cutting tip.
5. Reset previously placed wedges, where possible, after setting new wedges.
6. Inspect first piece on each plate.
7. Destroy paper template 4 h after it is made.

#### Torch settings

Preheat oxygen:	
High	235 kPa (34 psi)
Low	95 kPa (14 psi)
Preheat natural gas:	
High	7 kPa (1 psi)
Low (adjust by eye)	<7 kPa (<1 psi)
Cutting oxygen	485 kPa (70 psi)
Orifice diameter	1 mm (0.039 in.)
Speed	455 mm/min (18 in./min)

**Fig. 18** Gas cutting a part with three sides held to close tolerances (example 4). Dimensions in inches

was that melting would occur at the edges of the 25 mm (1 in.) wide area of the projection.

However, by using a high-speed cutting tip at the high end of the cutting-speed range (18 to 33 cm/min, or 7 to 13 in./min), both problems were overcome. A narrow kerf was cut in the slot, leaving a scrap width of 6.4 mm ( $3/4$  in.), which was sufficient to confine the flame. Heat buildup at the end of the projection was minimized by the cutting speed.

## Gas Cutting versus Alternate Methods

There are few gas cutting operations that cannot be performed by some type of machining. Machining may produce more accurate results, but time and cost may be saved by gas cutting. The two examples that follow describe applications in which gas cutting was used to remove a large quantity of metal, either to eliminate machining or to minimize the time required for machining to final size.

**Example 7: Gas Cutting versus Band Sawing.** The cross shown in Fig. 21(a) originally was rough cut by band sawing and then rough and finish milled to size. The cross was cut from a piece of forged 4340 steel, 48.9 by 29.2 by 13.3 cm thick (19 1/4 by 11 1/2 by 5 1/4 in. thick).

**Fig. 19** Gas-cut shape on which the narrow projection was subject to melting at the edges (example 5). Dimensions in inches

**Fig. 20** Shape that was gas cut to normal tolerance ( $\pm 3.2$  mm, or  $\pm 1/8$  in.) for 7.6 cm (3 in.) plate thickness, despite narrow re-entrant slot and thin projection, which ordinarily are subject to melting at the edges (example 6). Dimensions in inches

Because the shape could be traced by a single line set at the proper angle, gas cutting was substituted for band sawing, to save time. The cross was cut 7.6 mm (0.30 in.) oversize to allow for machining. A pantograph-type machine with a magnetic tracer was used for gas cutting. After a few trials to establish the best cutting sequence, the following operations were set up:

1. Set the torch to a compound angle consisting of a  $32.5^\circ$  bevel and left-to-right inclination of  $13.75^\circ$ . (The inclination angle caused some concern because the flame would lead the cut

#### Operating conditions for gas cutting

Cutting tip	Heavy-duty
Diameter of cutting-oxygen orifice	2.7 mm (0.1065 in.)
Diameter of preheat orifices (six)	1.2 mm (0.0465 in.)
Cutting-oxygen pressure	414-483 kPa (60-70 psi)
Cutting-oxygen flow rate	17-19 m <sup>3</sup> /h (600-680 ft <sup>3</sup> /h)
Preheat-oxygen flow rate (2-hose torch)	2.2 m <sup>3</sup> /h (77 ft <sup>3</sup> /h)
Acetylene pressure	41 kPa (6 psi)
Acetylene flow rate	2.0 m <sup>3</sup> /h (70 ft <sup>3</sup> /h)
Cutting speed	102-152 mm/min (4-6 in./min)

#### Man-hours per piece, band sawing

Drill starter holes	1.557
Band saw (rough size)	3.780
Rough mill (size, comparable to gas cut)	3.617
Total	8.954

#### Man-hours per piece, gas cutting

Load and unload furnace; set up block	0.113
Gas cut to size	0.495
Grind (clean up); handling	0.128
Total	0.736

**Fig. 21** Cross (a) that was gas cut, by method shown in (b), in approximately 8% of the time formerly required for producing it by band sawing (example 7). Dimensions in inches

at faces X and Y, Fig. 21b, and such a condition could possibly cause gouging.)

2. Preheat the block to 425 °C (800 °F) and soak for 6 min. (Permissible range was 320 to 480 °C, or 600 to 900 °F.)
3. Place the preheated block on the cutting table and align with a fixed steel template.
4. Make cuts 1 and 2 from left to right, as shown in Fig. 21(b). (Details of cutting are listed in the table with Fig. 21.)
5. Cool in air to room temperature, allowing complete transformation of the cut faces. (Immediate postheat treatment caused increased hardness of the cut faces.)

Actual time saved by gas cutting over band sawing was determined by comparing man-hours for both methods. This comparison, shown in the table that accompanies Fig. 21, indicates that gas cutting required less than one-twelfth the time needed for band sawing.

**Example 8: Gas Cutting versus Planing.** Many boiler drums for steam generators in power plants are made from two semicylindrical half shells welded together longitudinally to form a cylinder. The ends of the cylinder are then closed with formed heads joined to the shell by a circumferential weld. The half shells are hot formed in a press from flat steel plate. After forming, the excess material at the longitudinal joints must be removed before the shells are welded together; either planing or gas cutting can be used for this removal.

This example illustrates a saving that was achieved by gas cutting. To establish the cost advantage in removing excess metal from the longitudinal joints of boiler-drum half shells (Fig. 22) by gas cutting, as compared with planing, data from previous operations on shells of various lengths and thicknesses were compared.

Data for the planing operation were averaged from 83 half-shell operations. The planing cut was made at a speed of 7 m/min (23 sfm), feed of 1 mm/min (0.040 in./min), and 19 mm (0.75 in.) depth of cut, using a high-speed steel cutting tool.

For gas cutting, the half shells were submerged in water to a depth 25 mm (1 in.) below the line of cut, to prevent distortion. Two cutting torches were used in a special cutting machine, so that both edges of the shell could be cut simultaneously. Torch settings and travel speed were based on standard straight-line oxyacetylene

cutting of the same thickness. Over 60 cuts were made in the same range of thicknesses used for planing.

Data were translated into cost per foot, and the data indicated that, gas cutting cost approximately 64% less per half shell, on the average.

## Close-Tolerance Cutting

Shapes can be oxyfuel gas cut to tolerances of 0.8 mm ( $1/32$  in.) in plate up to 64 mm ( $2\frac{1}{2}$  in.) thick with multitorch pantograph or coordinate-drive machines. Conditions must be optimum:

- Operators must be well trained and experienced.
- Machines must be properly adjusted so that they can trace and retrace a pattern with an accuracy of  $\pm 0.13$  mm ( $\pm 0.005$  in.) in a given direction.
- Workpiece must be flat and free of dirt, scale, grease, and oil.
- Workpiece should be supported or restrained to prevent movement of the shape during cutting.
- Cutting tip must be clean (selected for high-quality, narrow-kerf cutting).
- Cutting speed and gas pressures should be tuned to specific production conditions.

Optical tracing devices can follow an ink line 0.64 mm (0.025 in.) wide on paper. If cutting speed does not exceed 760 mm/min (30 in./min), a template with an outside corner radius of 2.4 mm ( $3/32$  in.) will produce a sharp corner. A 2.4 mm ( $3/32$  in.) inside radius on the template produces a somewhat larger radius in the workpiece, depending on thickness and cutting tip. Numerical control tracing, whether punched tape or computer assisted, offers the greatest accuracy. Inaccuracies introduced by distortion of templates are avoided, and electronic directions are more exacting than those generated by mechanical cutting machines, which set limits on cutting speed.

## Oxyfuel Gouging

Oxyfuel gas gouging differs from ordinary gas cutting in that, instead of cutting through the material in a single pass, the process makes

grooves or surface cuts. Special cutting torches are required for most applications, although some gouging is done with standard torches and a special tip.

**Special cutting tips** for gouging vary in design, to suit the size and shape of the desired groove or surface cut.

A gouging tip for cutting flat grooves is shown in Fig. 23(a). Tips of this type are made in various sizes and shapes for manual or mechanical scarfing of billets and slabs, or for the removal of defects, pads, and fins from castings. Torches for these applications may include attachments for dispensing iron powder to increase the speed of cutting or to permit the scarfing of stainless steel. Gas consumption, especially of oxygen, is much greater than in ordinary gas cutting.

A gouging tip for cutting round grooves is shown in Fig. 23(b). The bent tip makes it possible to hold the torch so that the cutting flame will strike at a low angle. This type of gouging tip is used to remove defects from metal, such as in welds, or to cut a weld groove. A weld groove can be cut on the back of a welded joint to expose clean, sound metal for the final welding pass. Similarly, a weld groove can be cut in a butt joint between two plates.

**J-Grooves.** The tip shown in Fig. 23(a) also has been used to prepare the edges of thick-wall pressure vessels for welding by cutting a J-groove. Where plate edges with opposing J-grooves are butted together, a weld groove is formed (Fig. 24) that is more efficient, in thick sections, than a conventional V-groove. J-grooves are often made by planing, but oxyfuel gas gouging can be used to cut these grooves by a single pass in material up to 10 cm (4 in.) thick, and by two passes in thicker material.

J-grooves have been oxyfuel gas gouged in flat plates supported horizontally, so that droop from

**Fig. 22** Half shell from which excess metal of 7.7 cm (3.05 in.) average depth was removed by gas cutting at less cost than by planing (example 8). Dimensions in inches

**Fig. 23** Two types of gouging tips. (a) Tip for cutting flat grooves. (b) Tip for cutting round grooves

Pressure of preheat oxygen	207 kPa (30 psi)
Pressure of preheat acetylene	76 kPa (11 psi)
Pressure of cutting oxygen at nozzle	152 kPa (22 psi)
Consumption of cutting oxygen	184 m <sup>3</sup> /h (6500 ft <sup>3</sup> /h)
Vertical tip angle	19°
Horizontal tip angle	11 1/2°
Tip rotation angle	0°
Tip height	0
Tip offset	7.9 mm (5/16 in.)
Cutting speed	889 mm/min (35 in./min)

**Fig. 24** Weld groove formed from two J-grooves made by oxyacetylene gouging. Dimensions in inches

the cut at the vertical edge is driven out by the combined forces of the flame and gravity. However, the following example describes an attempt to cut the grooves in formed half shells, supported in a U-position with the joint edges horizontal. This was done to reduce setup cost, because the half shells had already been sized by gas cutting.

**Example 9: Cutting J-Grooves by Gouging.** After excess stock had been removed from boiler-drum half shells by gas cutting (example 8, Fig. 22), preparation of weld edges was required. Edge preparation consisted of cutting a J-groove along the longitudinal edges of the half shells. This was usually done by planing. In this application, however, large cost savings were possible if oxyfuel gas gouging could be used. The cost advantage would accrue mainly from using the same equipment and setup as was used for gas cutting to remove the excess stock.

The groove was changed slightly to accommodate the gouging technique. The objective was to provide a groove large enough to permit weld deposit into the root of the joint, but to minimize the cross-sectional area of the groove to reduce welding costs. Critical variables included gas flow and the position of the cutting tip relative to the cut. The tip was of the type shown in Fig. 23(a).

The three important angles of approach lay in planes taken through the axis of the tip. The vertical angle was in a plane at right angles to the surface to be cut, and it determined the angle of incidence of the flame to this surface. The horizontal angle determined the direction in which the molten slag would be driven from one side of the plate. The tip angle was the angle of rotation of the tip about its axis, and it determined the slope of the groove.

Other important dimensions were tip height (the distance of the tip from the surface), and tip offset, which determined the size of the root or uncured "land" on the surface to be cut.

A typical weld groove formed by abutting J-grooves gouged in this operation is shown in Fig. 24; conditions used for oxyacetylene gouging are listed in the accompanying table.

Gas gouging proved to be borderline for a trade-off with planing. A very high degree of skill was required to control all the variables in order to produce repetitive high-quality cuts. Material costs and the critical nature of the joints placed a heavy penalty on errors and defects. Because planing depended less on skill, and was quite dependable, this plant continued to use it for cutting J-grooves.

## Other Gas Cutting Methods

The basic oxyfuel method can be modified to allow gas cutting of metals, such as stainless steel and most nonferrous alloys, that resist continuous oxidation. Modifications of the oxyfuel method include metal powder cutting, chemical flux cutting (or flux cutting), and oxygen lance cutting.

## Metal Powder Cutting

Finely divided iron-rich powder suspended in a jet of moving air or dispensed by a vibratory device is directed into the gas flame in metal powder cutting. The iron powder passes through and is heated by the preheat flame, so that it burns in the oxygen stream. Heat generated by the burning iron particles improves cutting action. Cuts can be made in stainless steel and cast iron at speeds only slightly lower than those used for equal thicknesses of carbon steel. By adding a small amount of aluminum powder, cuts can be made through copper and brass.

**Thickness.** In plate 25 to 100 mm (1 to 4 in.) thick, powder cuts can be produced by machine to an accuracy of 0.8 to 1.6 mm ( $1/32$  to  $1/16$  in.). Heavier sections are seldom cut, except for the trimming of castings; in this application, hand cutting requires greater allowances to avoid damage. Typical metal powder cutting applications include removal of risers; cutting of bars, plates, and slabs to size; and scrapping.

**Quality of Cut.** The kerf has a layer of scale that, on stainless steel, flakes off as the workpiece cools. The surface exposed after scale removal has the texture of sandpaper. Light grinding is normally sufficient to smooth high

spots and remove iron particles and oxide. Unstabilized austenitic stainless steel may become sensitized by the heat of cutting. Powder-cut cast iron develops a hardened case at the surface, which may require annealing or removal by grinding.

**Equipment.** In metal powder cutting, a gas torch with an external powder attachment (Fig. 25), or a torch with built-in powder passages, is used. A vibratory or pneumatic powder dispenser (Fig. 26), air supply, and powder hose are required, in addition to fuel and oxygen lines. The equipment may be used manually for removing metal, such as risers from castings, or mechanized for straight-line or shape cutting by machine. Powder cutting torches mounted on gas cutting machines are capable of cutting stainless steel.

Powder dispensers may be of two general types: pneumatic and vibratory. Generally, all dispensers consist of a compressed air/nitrogen filter and regulator, a powder hopper, and a means of expelling the powder from the dispenser.

During operation of a pneumatic dispenser (Fig. 26), powder flow to the ejector unit is the result of gravitational force and the pressure differential between the discharge end of the air line in the ejector and the surface of the powder when the torch powder valve is opened. Compressed air (or nitrogen) passing through the ejector draws powder from the ejector baffle plate into the gas stream, forming an air-powder (or nitrogen-powder) mixture that then passes through the ejector outlet tube to the torch or

**Fig. 25** Powder cutting attachments. (a) Single-tube attachment. (b) Multijet attachment. (c) Enlargement of powder nozzle adapter

**Fig. 26** Pneumatic powder dispenser for use in metal powder cutting

lance. The ejector adjusting screw controls the amount of powder falling on the baffle plate; the regulator and the air throttling valve control the compressed air or nitrogen supplied to the ejector and the hopper. By manipulating the ejector adjusting screw, the regulator pressure, and the air throttling valve, the proper compressed air-powder (or nitrogen-powder) mixture can be obtained. This powder-conveying gas mixture is carried through a hose (6.4 mm, or 1/4 in., maximum diameter by 7.5 m, or 25 ft, long) connected to the cutting torch.

A removable cover that is fitted with a pressure-relief valve allows the hopper to be filled. A drying tray and a removable screen for eliminating oversized powder particles are also fitted into the top of the hopper.

*Vibratory dispensers* allow a quantity of powder to be dispensed from a hopper that is governed by a vibrator. Powder flow can be controlled by adjusting the amplitude of vibration.

Vibratory dispensers are generally used where uniform and accurate powder flow is required. Typical applications include precision cutting of materials, such as stainless steel, as well as production of high-quality, sharp top edges on cuts in carbon steels.

**Powder Selection and Production.** Many metallic and nonmetallic powders have been used for cutting operations. The ideal powdered solid fuel, whether metallic or nonmetallic:

- Exhibits nonhygroscopic action (does not readily absorb moisture)
- Liberates considerable heat during combustion
- Generates combustion products that flux refractory oxides
- Generates nonirritating and nontoxic combustion products
- Provides good process economy

Nonmetallic powders, such as sodium bicarbonate, remove refractory oxides by forming

**Table 11 Typical properties of atomized aluminum powder for metal powder cutting and lancing**

Screen analysis	
U.S. mesh	%
On 100	Trace
–100 + 200	52–67
–200 + 325	31–42
–325	0–4
Chemical analysis(a), %	
Aluminum	99.7
Iron	0.18–0.25 max
Silicon	0.12–0.15 max
Other metallics, each	0.01–0.03 max
Other metallics, total	0.15 max
Physical properties	
Apparent density	1.1 g/cm <sup>3</sup>
Tap density	1.4 g/cm <sup>3</sup>
Surface area	0.10–0.20 m <sup>2</sup> /g

(a) Chemical analysis excludes 0.4% aluminum oxide, which exists on the surface of the particles.

liquid slags that have a fluxing effect. Such powders, however, give off little or no heat. Consequently, cutting speeds are significantly slower than for metallic powders.

The most suitable metallic powders for cutting applications are iron and iron-aluminum blends. For metal powder cutting of stainless steel, iron powder can be used. For cutting oxidation-resistant materials other than stainless steels, blends containing iron and atomized –100 + 325 mesh aluminum powder are preferable.

*Iron powder* used for metal-cutting applications is produced by water atomization, or by a combination of granulation of molten iron by high-pressure water jets and chemical reduction.

*Aluminum powder* is sometimes added to iron powder to form blends used for cutting and lancing concrete, firebrick, difficult-to-cut nonferrous metals, and refractory-laden scrap, such as slag deposits on ladle pouring spouts. Table 11 provides data on cutting-grade aluminum powders that are produced by air atomization of molten aluminum.

*Powder blends* consisting of iron and 10 to 40 wt% Al are used to cut a variety of materials. Although preblended compositions consisting of iron and 15 wt% Al are available, iron and aluminum powders can be custom blended for specific applications, as shown in Table 12.

To blend powders properly, components should be poured simultaneously into a dry, nitrogen-filled container and tumbled for approximately 5 min. Additional blending occurs as the iron-aluminum powder is screened in the powder dispenser. Slight nonuniformities in the mixture have little effect on cutting performance.

**Table 12 Iron-aluminum blends used for cutting and lancing difficult-to-cut materials**

Nominal composition	Applications
Fe-10–15Al	Refractory scrap, thin nonferrous sections up to 25 mm (1 in.) thick
Fe-25Al	Aluminum, brass, bronze
Fe-30Al	Nickel, Monel, Inconel, Hastelloy, and concrete
Fe-40Al	Copper, brass, and bronze heavy sections 15 cm (6 in.) thick and up

**Powder-Cutting Apparatus.** Attachments for metal powder cutting are designed for use with conventional oxyfuel cutting torches. Attachments are available in three types: single-tube, multijet, and dual-tube. In addition to powder cutting attachments, specially designed powder cutting torches are available.

*Single-tube attachments*, which are clamped to a conventional machine or hand-held oxyfuel cutting torch, as shown in Fig. 25(a), externally discharge a single, uniform stream of powder into the cutting-oxygen stream at an angle of approximately 25°.

*Multijet attachments*, as shown in Fig. 25(b), are equipped with an adapter that fits over the standard cutting nozzle. The adapter (Fig. 25c) completely encircles the nozzle and feeds powder from a ring of ports through the preheat flames and into the cutting-oxygen stream.

*Dual-tube attachments* are used for high-capacity machine cutting torch applications in which the size and cost of a multijet attachment are prohibitive. Two powder nozzles are used to feed powder into the high-velocity cutting-oxygen stream.

*Powder cutting torches* are designed for manual powder cutting. Figure 27 shows a typical powder cutting torch. Depressing the cutting lever of the torches initiates the flow of both cutting oxygen and powder. The nozzles used in these torches are made from chrome-plated pure copper inserted into an abrasion-resistant sleeve.

**Applications.** Metal powder cutting is frequently used in cutting, scarfing, and lancing of oxidation-resistant materials. This type of metal cutting was originally developed for cutting stainless steels. The alloying elements (chromium and nickel) that impart desirable properties to stainless steels have made these steels difficult to process by conventional oxyfuel cutting. Chromium is the most detrimental; when oxyfuel cutting is applied to stainless steels, chromium, which has a high affinity for oxygen at elevated temperatures, immediately forms the highly refractory chromium oxide on the faces of the kerf and prevents further oxidation. These refractory oxides are melted and fluxed by the combustion of the powder particles during metal powder cutting. Table 13 gives typical operating conditions for cutting of 18-8 stainless steel.

**Fig. 27** Metal powder cutting torch

Nonferrous metals with the following thicknesses are suitable candidates for powder cutting:

Material	Thickness	
	cm	in.
Aluminum	25	10
Nickel	15	6
Brass and bronze	25	10
Copper	15	6
Hastelloy	16.5	6.5
Inconel and Monel	25	10

**Powder Scarfing.** In steel mills, powder metal cutting is used to scarf metals with alloy contents that are too high for oxyfuel scarfing. Typical applications include powder scarfing of large, bloomed ingots and small, unrolled ingots, slabs, and billets. Conditioning of these product forms by powder scarfing is less expensive and less time-consuming than mechanical methods such as grinding. Table 14 provides typical operating conditions for scarfing of 18-8 stainless steel.

**Powder lancing** is a piercing process in which the energy of the powder reaction is applied to oxygen lancing, thus permitting rapid, effective piercing of many materials that are difficult to pierce with a standard oxygen lance. These include iron and steel containing inclusions, reinforced concrete, firebrick, cinder block, aluminum billets, and sand and metal incrustations inside large castings.

Typical powder lancing applications include:

- Removal of blast furnace bosh plates
- Removal of large masses of iron (salamanders) that are deposited at the base of a blast furnace
- Cleaning of furnace linings

- Furnace tapping to remove slag
- Cleaning of soaking pits
- Removal of ladle skulls
- Piercing holes in reinforced concrete walls and floors

The efficiency of the powder lance in piercing reinforced concrete is preferred to the time-consuming, costly alternative of drilling with pneumatic tools.

### Flux Cutting

Flux cutting processes are well suited to materials that form refractory oxides, such as stainless steels. Finely pulverized flux is injected into the cutting oxygen before it enters the cutting torch. The torch has separate ducts for preheat oxygen, fuel gas, and cutting oxygen. When the flux strikes the refractory oxides that are formed when the cutting oxygen is turned on, it reacts with them to form a slag of lower-melting-temperature compounds. This slag is driven out, enabling oxidation of the metal to proceed. The operator should have an approved respirator for protection from toxic fumes generated by the process.

### Oxygen Lance Cutting

Oxygen lance cutting uses oxygen supplied at pressure through a consumable steel pipe or lance. Typically, an oxyfuel torch is used to heat the cutting end of the lance to a red heat, and then the oxygen flow is started through the lance. The lance or pipe begins to burn in a self-sustaining exothermic reaction at the burning end, and the preheat torch is removed. When the burning end of the lance is brought near the workpiece, the

work is melted by the heat of the flame. Lance tubes are normally sold in lengths of 3.2 m (10½ ft) with diameters of 16 mm (5/8 in.). More recent versions of the lance tubes have many small-diameter carbon steel wires packed into the steel tube to increase the cutting life and capability of the lance.

An experienced operator can pierce or cut through sections several feet thick by oxygen lancing. Protection is needed from flying sparks and molten slag or metal. Oxygen lancing can pierce nearly every material, including metals, reinforced concrete, refractory brick, mortar, and slag. The oxygen lance has also been used in underwater applications, having first been lighted before being placed underwater. Cutting oxygen is supplied at 550 to 830 kPa gage pressure (80 to 120 psig) and is controlled by a simple on-off valve at the end of the lance. The oxygen lance, in addition to being used for piercing, is also used to cut apart large steel plate structures. After September 11, 2001, this process was used extensively in cutting large fallen portions of the World Trade Center's structural steel into smaller, more easily moved pieces.

The discharge end of the iron pipe is preheated to ignition temperature, the valve at the opposite end of the pipe is opened gradually, and the oxygen burns off the end of the pipe, which is pressed gently against the metal to be cut or pierced. As the metal starts to react with the oxygen or melt from the heat generated by the burning pipe, the pipe is advanced to cut a hole somewhat larger in diameter than the pipe.

The action is continued until the work metal is completely penetrated or the pipe is burned to the minimum length for safe operation. Then, a new length of pipe is attached, and the process is resumed.

Severing requires a series of piercing operations along the desired line of cut, or washing along one side of the initial hole to form a slot. In the latter method, care must be taken to provide continual drain of molten slag and metal from the cut; otherwise, the entering pipe will overheat and burn up too fast, or the dross will solidify. Restarting the cut on solidified dross is difficult.

An oxygen lance is often used to make starting holes for cutting thick sections of steel and in heavy scrapping operations. The addition of powder to the oxygen has greatly improved the effectiveness of the lance on oxidation-resistant materials, such as cast iron, refractories, and concrete.

**Table 13 Typical oxyfuel gas powder cutting conditions for 18-8 austenitic stainless steel**

Note: Distance of nozzle from work: 64 mm (2½ in.); impingement angle: 30° (approximate); lateral angle: 50 to 10° (approximate); speed: 41 to 71 mm/s (96 to 168 in./min)

### Underwater Gas Cutting

In underwater gas cutting, an oxyhydrogen flame usually is preferred to oxyacetylene for preheat. Hydrogen is stable, and the flame is easily controlled at the higher pressures required for underwater operation. Oxynatural gas cutting is also used in underwater gas cutting, for the same reason.

The flame and the oxygen jet are shielded from the water by a cup that surrounds the cutting tip and into which compressed air is fed. The cup shield also serves as a guide by establishing the proper tip-to-work cutting distance. Air and gaseous products escape through slits in the shield. The higher heat input of oxygen-arc cutting is more efficient in cutting thicknesses of 9.5 mm ( $\frac{3}{8}$  in.) and less, because of the cooling effect of the water.

## Safety

The hazards of combustion or possible explosion associated with the gases used in OFC, as well as the presence of toxic gases and dust, make it necessary for the user to follow established safety precautions. The three areas of most concern, dealt with in this section, are protective clothing, handling and storage of gas cylinders, and the working environment.

**Protective Clothing.** Size, nature, and location of the work to be cut dictate the necessary protective clothing. The operator may require some or all of the following:

- Tinted goggles or face shield for light cutting, up to 25 mm (1 in.)—shade No. 3 or 4; for medium cutting, 25 to 150 mm (1 to 6 in.)—shade No. 4 or 5; and for heavy cutting, thicker than 150 mm (6 in.)—shade No. 5 or 6
- Hard hat and sometimes a close-fitting hat beneath
- Safety glasses
- Flame-resistant jacket, coat, hood, or apron; wear woolen clothing, not cotton or synthetic fiber; keep sleeves and collars buttoned, no cuffs; button-down pockets
- Protective gloves, wristlets, leggings, and spats. When cutting plated or coated stock,

respiratory protection should be used if necessary.

- Clothing should be free of grease and oil, and free of ragged edges.

**Cylinders.** Fuel gas cylinders should be placed in a location where they cannot be knocked over. Cylinders should be kept upright, with valve ends up to avoid hazardous liquid withdrawal; the protective caps should never be removed, except when the cylinders are connected for use. Cylinders should never be exposed to high heat or open flame, which could cause them to explode.

Cylinders should not be placed where they may complete an electric circuit, such as against a welding bench. They should not be used as an electrical ground or as a surface on which to strike an arc.

Damage to cylinders by impact should be avoided. Regulators should be removed before cylinders are moved, except on portable outfits. Slings or magnets should not be used as supports or rollers.

Damaged or defective cylinders should be removed from service immediately, tagged with a statement of the problem, and returned to the supplier. Leaking cylinders should be transported to an isolated location outdoors, the supplier notified, and his instructions for disposal followed.

No attempt should be made to fill a small cylinder from a large one. Filling requires special equipment and training.

Before storing, valves should be closed and caps replaced on empty or unused cylinders. Empty cylinders should be marked accordingly and kept separate from filled ones. Unused oxygen or fuel gas should not be drained from cylinders, and oxygen cylinders should be kept away from fuel gas cylinders.

**Working Environment.** Torches should not be used around chlorinated solvent vapors; heat forms phosgene and other corrosive, toxic products from them. Adequate ventilation must be provided, especially when alloys containing lead, cadmium, zinc, mercury, beryllium, or other toxic elements are being cut. A flame should not be used in a closed vessel or pipeline that has held flammable or explosive material, such as gasoline. Adequate ventilation should also be provided when work is being performed in a confined area. Under such conditions, the person doing the cutting should have an assistant, in case trouble occurs.

Fire-prevention warnings in “Safety in Welding and Cutting” (ANSI/AWS 249.1), which have legal status as Occupational Safety and Health Administration (OSHA) regulations, should be heeded. Workers should know the locations and operating procedures of the nearest fire extinguishers.

If cutting is to be done over concrete, it should be protected with metal or another suitable material; concrete spalls explosively when overheated. Hoses should be protected from sparks, hot slag, hot objects, sharp edges, and open flame.

# Electric Arc Cutting

**ELECTRIC-ARC CUTTING** is a method of melting or oxidizing metal by applying heat from an electric arc to the work-metal surface along a line of cut. Because of the extremely high temperature developed, the electric arc can be used to cut any metal that conducts electricity. Modifications of the basic process include the use of compressed gases to cause rapid oxidation (or to prevent oxidation) of the work metal, thus incorporating some aspects of gas cutting.

Electric-arc cutting includes several processes, of which the following are of commercial importance: air-carbon arc cutting, oxygen arc cutting, plasma arc cutting, and the Exo-Process. Other, seldom-used processes, which largely have been superseded by the aforementioned, are briefly described in the last section of this article.

Electric arc cutting can be used on ferrous and nonferrous metals for rough severing, such as removing risers or scrap cutting, as well as for more closely controlled operations. Each process has particular capabilities and limitations. Special applications include shape cutting, grooving, gouging, and underwater cutting. Maintaining the squareness of cut edges, particularly in sections more than 50 mm (2 in.) thick, is generally more difficult in electric arc cutting than in gas cutting.

## Plasma Arc Cutting\*

Plasma arc cutting (PAC) is an erosion process that utilizes a constricted arc in the form of a high-velocity jet of ionized (electrically conductive) gas to melt and sever metal in a narrow, localized area. The arc is concentrated by a nozzle onto a small area of the workpiece. The metal is continuously melted by the intense heat of the arc and then removed by the jetlike gas stream issuing from the torch nozzle. The PAC process relies on heat generated from electrical arcing between the torch electrode and the workpiece. It generates very high temperatures (28,000 °C, or 50,000 °F, compared to 3000 °C, or 5500 °F, for oxyfuel cutting) and does not depend on a chemical reaction between the gas and the work metal. Therefore, plasma arc cutting can be used on almost any material

that conducts electricity, including those that are resistant to oxyfuel gas cutting. This traditional mode is referred to as transferred arc cutting. Another mode is the nontransferred arc method, which can cut nonmetallic objects (such as rubber, plastic, styrofoam, fabric, and wood) with a good quality surface to within 0.50 to 0.75 mm (0.020 to 0.030 in.) tolerances.

Plasma arc cutting was originally developed for cutting nonferrous metals using inert gases. Modifications of the process with the use of oxygen or compressed air in the orifice gas also permit the cutting of carbon and alloy steel with improved cutting speeds and a cut quality similar to that obtained with oxyfuel cutting. Plasma arc cutting can reach high cutting speeds (Fig. 1) with productivity increases over that of oxyfuel gas cutting without increasing space or machinery requirements. Plasma arc cutting of carbon steel plate can be done faster than with oxyfuel gas cutting processes in thicknesses below 75 mm (3 in.) if the appropriate equipment is used. For thicknesses under 25 mm (1 in.), plasma arc cutting speed can be up to five to eight times greater than that for oxyfuel gas cutting

(Fig. 2). For thicknesses greater than 38 mm (1½ in.), the choice of plasma arc or oxyfuel

**Fig. 1** Typical cutting speeds for PAC of carbon steel or stainless using 6.8 m³/h (240 ft³/h) of air at 345 kPa (50 psi) from a single source. This information represents realistic expectations using recommended practices and well maintained systems. Other factors such as parts wear, air quality, line voltage fluctuations, and operator experience may also affect system performance.

**Fig. 2** Comparison of oxyfuel gas cutting and PAC of plain carbon steel

\*Adapted from C. Landry, Plasma Arc Cutting, *Welding, Brazing, and Soldering*, Vol 6, ASM Handbook, ASM International, 1993, p 1166-1171

gas cutting depends on other factors such as equipment costs, load factor, and applications for cutting thinner plates and nonferrous metals. Characteristics of plasma arc cutting and oxyfuel gas cutting are compared in Table 1.

## Operating Principles

The basic plasma arc cutting torch is similar in design to that of a plasma arc welding torch (Ref 1). In its simplest form, a PAC system includes a gas-cooled torch with leads that connect to a power supply (Fig. 3). The basic components include:

- A torch designed for either manual or mechanized operation
- Torch leads that carry the electric power, gas, and coolant to the torch
- A coolant system for the torch
- A power supply that provides the proper current and voltage for the plasma arc
- A manifold system for combining power, gas, and coolant for connection to the torch
- A control system that consists of switches, gages, dials, meters, and other controls for operating the PAC system and the gas supply

In the PAC process, a cool and inert gas, such as compressed air, is forced under pressure through a small orifice in the front of the cutting torch. This torch is connected by leads to a direct current (dc) power supply. In the torch, a portion of the inert gas is changed into a plasma (ionized gas) by heat created by the discharge of a high-voltage arc from the power supply. This arc is created between an electrode (dc negative) in the torch and the tip (nozzle) of the torch through which the gas flows.

The basic plasma arc cutting circuitry is shown in Fig. 4. The process operates on direct current, straight polarity (dcsp), electrode negative, with a constricted transferred arc. In the transferred arc mode, an arc is struck between the electrode in the torch and the workpiece.

The arc is initiated by a pilot arc between the electrode and the constricting nozzle. The nozzle is connected to ground (positive) through a current-limiting resistor and a pilot arc relay contact. The pilot arc is initiated by a high-frequency generator connected to the electrode and nozzle. The welding power supply then maintains this low-current arc inside the torch. Ionized orifice gas from the pilot arc is blown through the constricting nozzle orifice. This forms a low-resistance path to ignite the main arc between the electrode and the workpiece. When the main arc ignites, the pilot arc relay may be opened automatically to avoid unnecessary heating of the constricting nozzle.

When a small amount of dc from the power supply is imposed on this high-voltage arc, it achieves a pilot arc that extends approximately 13 mm ( $\frac{1}{2}$  in.), as a plasma jet from the tip orifice. This pilot arc acts as a path that establishes the main cutting arc to the workpiece. When the pilot arc is brought in contact with the metal workpiece, which is connected to the positive side of the dc power supply, the transferred (main) arc occurs and the pilot arc is shut off.

The cutting torch is usually operated with a standoff, that is, the distance between torch and workpiece. Standoff distance may vary from approximately 3 to 10 mm ( $\frac{1}{8}$  to  $\frac{3}{8}$  in.) to about 5 to 20 mm ( $\frac{1}{4}$  to  $\frac{5}{8}$  in.) for some machine-operated plasma arc torches. In some applications, the torch tip can actually be dragged along the workpiece. The transferred plasma arc heats the metal by the combined effects of the electric arc from the power supply, the high-temperature plasma created by constriction of the arc by the orifice, and the reassociation of the gas molecules at the workpiece. The molten metal is blown out of the cut, or kerf, by the high-velocity, well-columnated plasma jet, resulting in fast, clean cuts.

## Equipment

**Plasma Arc Cutting Torches.** All plasma arc torches constrict the arc by passing it through an orifice as it travels away from the electrode and

toward the workpiece. The basic design and terminology for a PAC torch are shown in Fig. 5. The tip, or nozzle, of the torch contains the orifice that constricts the arc. The diameter of the orifice, which ranges from 1 to 6.4 mm (0.038 to 0.250 in.), determines the maximum cutting current that can be used with that tip. The larger the orifice, the more current that can be forced through it. As the orifice gas passes through the arc, it is heated rapidly to high temperature, expands, and accelerates as it passes through the constricting orifice. The intensity and velocity of the arc plasma gas are determined by such variables as the type of orifice gas and its entrance pressure, constricting orifice shape and diameter, and the plasma energy density on the work.

Because the plasma constricting nozzle is exposed to the high plasma flame temperatures (estimated at 10,000 to 14,000 °C, or 18,000 to 25,000 °F), the nozzle is sometimes made of water-cooled copper. In addition, the torch should be designed to produce a boundary layer of gas between the plasma and the nozzle. Cooling of PAC torches that operate at less than 150 A can be simply accomplished by properly channeling the gases used in torch operation. High-powered systems require a water-based coolant system, which consists of a reservoir, pump, and heat-exchanger assembly. Because this type of coolant is often in contact with both negative and positive electric potentials within the torch, it is important to use a deionized (nonconductive) coolant.

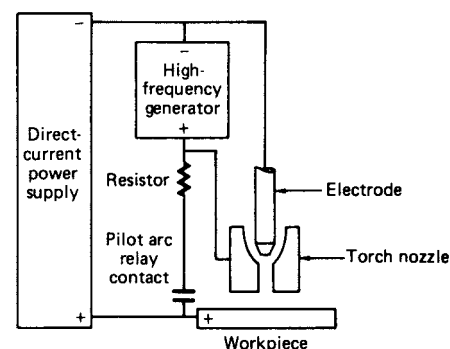

Tips are designed so that the orifice provides maximum arc constriction. If a tip orifice is over-powered, then it will become gouged or washed out, resulting in a change of arc characteristics and in the deterioration of cut quality and cutting speed. To attain optimal cutting conditions, tips are used at or very near their maximum cutting rating. Torch tips are either water cooled, through internal passages connected to a closed-loop coolant system, or indirectly cooled, by good thermal contact with other torch parts that are either water or gas cooled.

**Table 1 Comparison of oxyfuel gas and PAC processes**

	Oxyfuel	Plasma arc
Flame temperature	3040 °C (5500 °F)	28,000 °C (50,000 °F)
Action	Oxidation, melting, expulsion	Melting, expulsion
Preheat	Yes	No
Kerf	Narrow	Wide
Cut	Both sides square	One side square
Speed	Moderate	High
Heat-affected zone	Moderate	Narrow
Cutting ability:		
Carbon steel	Yes	Yes
Stainless steel	Requires special process	Yes
Aluminum	No	Yes
Copper	No	Yes
Special alloys	Some	Yes
Nonmetallics	No	Yes

**Fig. 3** Typical PAC torch

**Fig. 4** Plasma arc cutting circuit. The process operates on direct current electrode negative (straight polarity). The arc is initiated by a pilot arc between the electrode and torch nozzle. Pilot arc is initiated by the high-frequency generator, which is connected to the electrode nozzle.

The electrode, or cathode, in a PAC torch is the surface from which the plasma arc is generated. This electrode is in electrical contact with the negative potential in the power supply. Both electrode material and design are quite varied. For most applications that use nitrogen or argon-hydrogen as the plasma gas, a 2% thoriated tungsten is used as the electrode. Hafnium and zirconium are commonly used as electrode materials for both air and oxygen plasma cutting.

In terms of its construction, the electrode can be solid, such as a rod of tungsten or a tungsten element held in a solid-copper holder, or it can be hollow and have two pieces (copper and the electrode element) that allow direct water or gas cooling. Because proper cooling will promote both tip and electrode life, PAC torches designed for cutting above 150 A are usually water cooled.

In the area between the electrode and the tip orifice, which is called the plenum, the initial ionization or plasma formation takes place. The plasma gas enters the plenum in either a straight (laminar) flow pattern or a tangentially swirling pattern. Although torch design depends on several factors, pointed electrodes usually utilize laminar flow patterns, whereas flat or blunt-ended electrodes utilize a swirling gas to keep the arc attachment point moving around the center of the electrode. The swirl is most commonly imparted on the gas by a gas distributor, or swirl ring, that is located near the end of the electrode.

Other parts that are common to most PAC torches include internal ceramic or high-temperature plastic insulators for electrical insulation, collets or other mechanisms for retaining the electrode, and shield cups to insulate the front end of the torch from the workpiece.

**Leads.** The PAC torch is connected to the other system components by means of a leads package that consists of hoses, fittings, and wires. The leads supply the electric power, gases, and cooling medium to the torch. Lead lengths vary from 3 to 68 m (10 to 225 ft), depending on the application. Simple extension kits can be used to join leads packages together for increased length.

**The power supply** for a PAC system must have a dc output with the negative side connected to the electrode in the torch and the positive side connected to the workpiece. Systems that include a pilot arc also have a positive connection, limited in current through a resistor, to the tip in the torch. Power supplies are usually of a constant-current, dropping volt-amp curve design, and they have higher open-circuit voltages (up to 400 V) than those found in common welding power supplies, in order to accommodate the high operating voltage (90 to 200 V) of the torches. The amperage output of power supplies can be designed to have one fixed level, or several switchable fixed settings, or an infinitely adjustable output by means of a control potentiometer.

**The manifold assembly** combines the dc power, gas, coolant, and high-voltage starting circuitry and provides it to the cutting torch via the leads package.

**Controls** for starting and stopping the cutting operation, selecting the proper amperage output, adjusting gas flows, and regulating other system functions can be located on the manifold box, on the power supply, or in a dedicated control cabinet for convenient mounting near an operator station.

All-in-one packaged PAC systems that combine the coolant system, power supply, manifold assembly, and controls in one unit are available. These systems offer improved portability, simplicity of operation, and reduced costs.

**Optional equipment** for manual PAC systems includes drag-type shield cups with protrusions, or feet, that enable direct contact with the workpiece to allow the operator to maintain a constant standoff. Wheels that can be attached to the torch for manual guidance, as well as circle-cutting attachments that include an adjustable radius rod to allow the cutting of various-sized holes, are also available.

Optional equipment for mechanized PAC systems includes torch-standoff controls that automatically find and maintain the proper standoff for the cutting operation. Water-shrouded

systems are also available. When used in conjunction with water tables, these systems provide a blanket of water around the front of the torch during the cut, in order to minimize smoke, fumes, noise, and arc glare.

**Machine Ratings.** In selecting a plasma cutting unit, the thickness of plate to be cut and the required cutting speed should be considered. Table 2 shows thickness capacity and midrange cutting speeds of four plasma units. These ratings are an average of speeds quoted by two manufacturers of plasma arc cutting equipment.

The thickness capacity of a cutting unit should first be examined to determine the cutting speed it can achieve for a given application. Next the speeds quoted for the next-larger unit should be studied to see whether the greater speed justifies its higher cost. For example, a 30 A unit cuts 6 mm (1/4 in.) stainless steel plate at 125 to 250 mm/min (5 to 10 in./min); the 50 A unit cuts 6 mm (1/4 in.) plate at 635 to 1270 mm/min (25 to 50 in./min), a significant increase. If the average required cutting thickness exceeds 75% of the maximum thickness capacity of a unit, the next larger size should be considered.

Pierce capacity is usually half the cutting thickness capacity, an important consideration in selection of plasma equipment. To cut plate thicker than 75 mm (3 in.), connecting 400

or 500 A units in parallel extends thickness capacity.

## Gases

Any gas or gas mixture that does not degrade the properties of the tungsten electrode or the workpiece can serve as a plasma gas. The gas mixture varies according to the plasma equipment design criteria. The most commonly used gas is compressed air; all common metals, such as carbon and alloy steels, stainless steels, and aluminum, can be cut with compressed air. As the metal thickness increases (over 25 mm, or 1 in., with steels and stainless steels), benefits are derived from the use of nitrogen plasma with CO<sub>2</sub> shielding. Aluminum cut quality is improved using argon-hydrogen plasma and nitrogen as the secondary gas blanket. When high-duty cycles are used, a change from compressed air to nitrogen/CO<sub>2</sub> prolongs the consumable life.

The plasma or secondary shielding gases that are used in PAC systems are inert, and they are usually supplied from high-pressure cylinders, bulk tanks, or air compressors. Pressure regulators are adjusted to provide from 140 to 560 kPa (20 to 80 psi) of gas, depending on system requirements.

If water is used in place of a secondary gas, then it is usually supplied from a filtered, in-plant water system at a flow rate of 0.63 to 1.9 L/min (10 to 30 gal/h), again, depending on system requirements.

The purity of plasma gases is usually of a welding grade or higher. The plasma gas can be compressed air, which is inexpensive and provides fast, clean, high-quality cuts on carbon steels, but a relatively short electrode life, because of the rapid oxidation that occurs at high temperatures. If purity from an in-plant compressor is a problem, then either charcoal filters that remove oil vapors and moisture traps or dryers can be added into the line. As an alternative, clean, dry, compressed air can be obtained in cylinder form.

Another choice is nitrogen, which is relatively inexpensive and provides good-quality cuts on stainless steels and aluminum. It also provides good electrode life.

Argon-hydrogen, which is usually supplied in a 65 or 70% Ar and a 35 or 30% H mixture, operates at a higher temperature. It can reduce the quantity of smoke and fumes created during the cutting operation and provide a higher-quality surface finish on aluminum and stainless steels that are more than 13 mm (0.5 in.) thick. However, argon-hydrogen is usually from two to three times more expensive than nitrogen. In addition, it is not as readily available and requires more-critical adjustment of the operating parameters.

Oxygen plasma provides the same benefits as air plasma when cutting carbon steels. Because of the absence of nitrogen, it can minimize the amount of nitrides in the cut surface, thereby

enabling better-quality welds on "as-cut" pieces that have not undergone additional finishing operations. Like air plasma, oxygen causes more rapid electrode erosion than does nitrogen or argon-hydrogen plasma.

## Operating Sequence

A routine check of the PAC system before power is applied involves examining the torch to ensure proper assembly, verifying adequate coolant and gas supplies, and inspecting all components of the system to verify that they are in order.

The disconnect switch can then be turned on, which applies power to the system. Gas supplies should be turned on and adjusted according to the recommended pressure or flow. The plasma gas should be allowed to purge for an additional 2 to 3 min in order to eliminate any traces of moisture that accumulated within the plasma lines. This moisture is usually the result of condensation that forms when the system is off for prolonged periods of time.

The "start-cut" signal can be supplied by either an operator who simply pushes a start button on a mechanized control station to energize the switch on a manually operated torch or by a computer-generated signal on a fully automated system. The start-cut signal will cause the main contactor in the power supply to energize and initiate a gas prepurge. The prepurge ensures that gas is at the torch before an arc is struck and can last from 2 to 10 s if extra-long torch leads are used. At the end of the prepurge, the high-frequency arc and pilot arc circuits are energized, establishing the pilot arc at the torch. The pilot arc duration can be controlled by a timing circuit, limiting it to approximately 5 s, or it can be continuous, thereby shutting off only after an actual cut is established. Some PAC systems include circuitry for an automatic restart pilot, which enables automatic cycling between the pilot and cut modes as long as the start signal is present. This type of operation is valuable when cutting expanded metal, grating, or other material with an interrupted cut line.

The cutting arc will begin as soon as the torch and pilot arc are brought close enough to the workpiece (usually, 13 to 25 mm, or 1/2 to 1 in.) to allow main arc transfer. However, some systems do not use a pilot arc to start the torch. Rather, they only use high frequency and require that the torch be placed within 1 mm (0.038 in.) to establish a cutting arc. The cutting action will continue as long as there is metal to which the arc can transfer. If the cutting speed is too fast, then the arc will not fully penetrate the metal, and an incomplete cut or gouge will occur. If the cutting speed is too slow, then the kerf will widen as available metal is blown away and, eventually, the arc will be extinguished.

When the "start signal" is removed, or when a stop signal is provided, the cutting arc or pilot arc will shut off and the system will enter a post-purge mode, which is a continuation of plasma

gas flow for 2 to 40 s to ensure that the electrode cools in a good atmosphere and to remove any residual heat within the torch. The system is then ready for the next start signal to begin the cutting sequence again. Some systems include circuitry that allows immediate starting of the pilot or cutting sequence at any time during the post-purge.

For manual operation, the torch is usually held with two hands to provide optimum comfort and speed control. An exception to this rule occurs when small, lightweight torches are used in conjunction with templates or a straight edge that requires one hand to be used for positioning while the other hand operates the torch. In manual operation, the current and rate of gas flow are set, and the arc is struck by pressing a button on the torch, which is guided manually over the work.

There are two means of starting the cut in manual PAC systems: edge starts and pierce starts. For edge starting, the torch tip is usually placed directly over the edge of the workpiece. Resting the torch at the start position ensures that the cut will begin at the proper location. The torch switch is pressed, and the torch is moved along the cut line as soon as the arc is established. At the end of the cut, the arc is automatically extinguished, and the control opens the contactor and closes the gas valves. The operator can extinguish the arc at any time by moving the torch away from the work metal.

Piercing is best accomplished by slightly angling the torch over the starting point so that the molten metal is directed away from the torch. After starting the arc, the torch is moved to the vertical position and the cut proceeds along the cut line. This technique prevents molten metal from blowing back at the torch and causing damage. Thicker metals may require that the torch be left stationary over the start point for a few seconds to ensure full arc penetration. Because a pierce will sometimes result in a blow hole that is larger than the normal kerf width, it is good practice to start the pierce off the cut line in the scrap piece to eliminate discontinuities in the cut surface of a good piece.

In mechanized applications, edge starts are accomplished by lining the torch up with the cut line. Pierce starts cannot be done in the same way as they are in manual cutting, because the torch cannot be conveniently angled and then brought back to a vertical position. Best results are achieved with a slow-moving pierce, in which the torch motion begins when the arc is struck. This allows the molten metal to flow back along the cut line until full penetration is achieved. Some allowance should be made for the start of a moving pierce to ensure that the entire piece is cut out.

A third means of starting the arc in mechanized applications is the running-edge start. In this mode, the torch is positioned off the workpiece, the pilot arc is established, and then the torch is put in motion. The cutting arc is established as soon as the pilot hits the edge of the work.

For either manual or mechanized operation, the best cut quality is usually achieved with a torch standoff of 3 to 10 mm ( $1/8$  to  $1/2$  in.). Thinner metals, under 3 mm ( $1/8$  in.) thick, require a closer standoff. At low power levels (below 40 A), good-quality cuts can be obtained by dragging the torch tip in contact with the work.

The proper cutting speed for achieving the best quality is determined by the angle that the arc makes with a vertical plane as it exits the workpiece (Fig. 6). The optimal speed for air cutting is usually achieved when the arc is vertical ( $0^\circ$ ). Nitrogen and argon-hydrogen cuts are optimized by adjusting speed to obtain a  $5$  to  $10^\circ$  trailing arc. The best oxygen cuts are made using a speed that provides a slight ( $1$  to  $2^\circ$ ) leading arc. The PAC torch should always be kept square with the workpiece to provide maximum arc penetration and to obtain consistent quality when contour cutting.

### Process Variations

The conventional PAC torch, utilizing the basic system components described earlier, uses only a single gas. Because conventional torches

do not incorporate any secondary gas, they must be liquid cooled.

Several process variations involve auxiliary shielding in the form of gas or water to improve the plasma arc cutting quality for particular applications. They are generally applicable to materials in the 3 to 38 mm ( $1/8$  to  $1\frac{1}{2}$  in.) thickness range, depending on the current rating of the plasma machine.

**Dual-flow plasma cutting**, also referred to as gas-shielded PAC, provides a secondary gas blanket around the arc plasma, as shown in Fig. 7. The usual orifice gas is nitrogen or compressed air. The shielding gas is selected for the material to be cut. It may be compressed air for mild steel,  $\text{CO}_2$  for stainless steels, and an argon-hydrogen mixture for aluminum. The torch design provides special passages for this secondary gas. The functions of the secondary gas are to:

- Assist the plasma in blowing away molten metal
- Enable faster and cleaner cuts
- Provide better cooling of the torch front end
- Reduce accumulation of metal spatter on the torch
- Reduce top-edge rounding of the workpiece

Fig. 6 Arc characteristics of PAC torch

- Permit easier piercing
- Minimize double arcing

In gas-cooled, rather than liquid-cooled, torches, it is the secondary gas that provides the cooling action. The choice of secondary gas can also affect cut quality, cutting speed, and the amount of smoke and fumes produced during the PAC process.

**Water-shielded PAC** is a variation of the gas-shielded process that is only used in mechanized applications. The water, which can be provided from standard plant water systems at a rate of 0.63 to 0.95 L/min (10 to 15 gal/h), is substituted for the secondary gas in torches designed for this type of operation. Using a water shield, rather than a gas shield, is less expensive. The water shield helps to significantly reduce the level of noise, arc radiation, and fume generated from the plasma cutting operation. It also results in reduced top-edge rounding and fumes, and a clean, shiny, cut surface.

**Water-injection PAC** is similar to the water-shielded process, except that the water is forced into the plasma stream, at approximately 1.26 L/min (20 gal/h), just after the arc exits the tip orifice and just before it leaves the ceramic piece on the front end of the torch (Fig. 8). The impinging water increases the constriction and density of the plasma arc, resulting in improved cut squareness and increased cutting speed. Because of the entry of water at the tip orifice in a water-injection torch, the quality of water is more critical than that used in water-shielded cutting. A plant water system that has high levels of dissolved minerals may require water softeners in conjunction with the system in order to avoid rapid deterioration of part lifetimes. Water-injection cutting is only used in mechanized setups.

### Process Capabilities

Plasma arc cutting is unique in its ability to make fast, clean cuts on both ferrous and

Fig. 7 Dual-flow PAC

nonferrous metals. When compared with the oxyfuel cutting of ferrous metals, the major advantage of this process is its speed, which can be from four to five times greater than the speed of oxyfuel cutting. For example, when cutting 6 mm (1/4 in.) carbon steel with an oxyfuel process, a speed of 0.68 m/min (27 in./min) is used, but when using a 150 A PAC system with air plasma, the speed goes up to 3.81 m/min (150 in./min) (Fig. 9). Because labor and overhead represent the primary costs of operating a mechanized cutting system, reducing the time to cut a part will, in turn, reduce the cost of the part itself. The fivefold increase in cutting speed of the PAC process, versus that of the oxyfuel process on carbon steel, will translate to a part cost of only one-fifth that achieved with the oxyfuel process.

Because the speed of the PAC process, like that of the oxyfuel process, is dependent on metal thickness, increasing thickness will diminish the speed advantage. Therefore, other factors that favor the PAC process have to be determined when comparing it with the oxyfuel process for cutting carbon steel that is more than 50 mm (2 in.) thick.

Another advantage of the PAC process, versus the oxyfuel process, is its ability to cut carbon steel with virtually no distortion, because of the fast travel speed and narrow, localized heating of the metal. This same high-speed localized

heating results in a much narrower heat-affected zone (HAZ), that is, the depth of metallurgical change from the cut surface, than that of the oxyfuel process. Typical HAZs of up to 1.78 mm (0.070 in.) from oxyfuel cuts on carbon steel have been measured, whereas the PAC process produces HAZs of only 0.51 mm (0.020 in.). The HAZ will have an effect on the overall strength, corrosion resistance, and susceptibility to surface cracking of the cut part. If the application is such that the cut part must undergo machining to remove the HAZ, then the depth of machining required is much less with the PAC process.

Normally, PAC surfaces do not require any additional finishing operations before they are welded, although this usually depends on the final application and the codes to which the cut part being welded must conform.

The PAC process has the ability to make both edge starts and pierce starts without a preheat, as is required for oxyfuel cutting. This advantage becomes quite dramatic when the application calls for interrupted cuts, such as on grating or expanded metal.

These same capabilities apply to the cutting of stainless steel and aluminum. No preheat is required, and there is no distortion of the cut part. For plasma arc cuts on stainless steel and aluminum, respectively, the HAZ has been measured at 0.25 and 2.03 mm (0.010 and 0.080 in.).

### Process Mechanization

Plasma arc cutting can be mechanized in several ways, the simplest of which takes the form of portable carriages or tractors. These devices can travel along a track to achieve straight-line cutting or along an arc guided either by a radius rod or by hand to cut curves. Although tractors are primarily used for simple cutoff, squaring, and trimming operations, they

are also used as parts of large fixtures for cutting cast and rolled metals.

Pattern/follower wheel-shaped cutting machines or pantographs are used for the plasma arc cutting of relatively small, simple shapes. A scale model of the desired piece is held and traced by a follower that is connected, through a series of arms, to the torch, which cuts either an identical or a larger-scale part.

Optical tracing or electric-eye machines are used to trace part shapes that are in the form of templates or, more commonly, in the form of line drawings that are the same scale as the desired part. A mechanized PAC setup that uses optical tracing is shown in Fig. 10. The speed of an optical tracing machine is limited by the capability of the electric eye to follow a line. Low-speed machines that operate at speeds up to 1.52 m/min (60 in./min), which were originally designed for use with oxyfuel torches, are compatible with lower-amperage PAC systems. New high-speed machines, with speeds of up to 12.7 m/min (500 in./min), have been developed for operation with high-amperage plasma cutting systems.

Computer numerical control (CNC) shape-cutting machines with speeds of up to 25.4 m/min (1000 in./min) represent the state-of-the-art in automated cutting. CNC machines are much more reliable, have greater capabilities, and are lower priced than their numerical (tape) control machine predecessors, which are now considered obsolete. CNC machines can be connected directly into the central processor (direct numerical control) of a plant for complete integration of product design, material requirements, work in process, and other functions. Because the evolution of CNC machines paralleled that of mechanized PAC systems, their combination represents the highest level of productivity available in metal cutting today.

Automated material handling systems are sometimes used to keep up with the speed of CNC PAC systems. Typical systems utilize a

Fig. 8 Water injection PAC arrangement

Fig. 9 Cutting speeds versus mild steel thickness (150 A, air plasma)

Fig. 10 Mechanized PAC system that uses optical tracing of part shapes

raw material loading station, a cutting station, and a finished parts station. While the cutting operation is taking place, the operator is loading raw material and unloading finished parts. Upon completion of the cutting sequence, a conveyor moves the finished parts off the cutting area as it moves raw material onto the cut station. The operator signals the start-cut sequence and the cycle is repeated.

Robots are being used in increasing numbers for PAC operations involving the contour cutting of pipe and vessels, the removal of sprues and risers from castings, and the cutting of shapes in various planes of cast or formed parts. Material handling is also a great concern in robotics applications. Multiple workstations are the rule, because they allow an operator or another robot to load unfinished work and remove finished parts while the cutting operation is ongoing.

### Quality of Cut

Most plasma cutting torches impose a swirl on the orifice gas flow pattern by injecting gas through tangential holes or slots (Fig. 7, 8). As a result of the swirl of the plasma gas, walls of plasma arc cuts have a V-shaped included angle of 2 to 4° on one of the cut edges. When a straight edge is required on the cut part, the operator must operate the torch carefully so that the bevel is on the scrap side of the cut. When the operator is facing the direction of torch travel, if the gas swirls clockwise, the bevel will be on the left side of the cut. In many cases, a small bevel is acceptable; it may even be used as a weld preparation. The relationship of torch travel direction to the part with clockwise swirl of the orifice as is illustrated in Fig. 11.

Quality of cut includes surface smoothness, kerf width, degree of parallelism of the cut faces, dross adhesion on the bottom of the cut, and sharpness of top and bottom faces. Table 3 provides data on the causes of imperfections in plasma arc cutting of low-carbon steel, stainless steel, and aluminum. Besides the HAZ, the quality of a plasma arc cut involves the following factors (Fig. 12):

- Cut angle
- Dross
- Surface finish

- Top-edge squareness
- Kerf width

**Cut Angle.** Plasma arc cutting will usually result in an angle on the cut surface of approximately 1 to 3° on the “good” side and 3 to 8° on the “bad” side, when using torches that swirl the plasma. With laminar-flow torches, the angle on both sides is usually about 4 to 8°. These angles are most noticeable in mechanized applications where the torch is square to the workpiece. The good and bad sides of the cut are determined by torch travel direction and plasma gas swirl. With a clockwise gas swirl, the good side of the cut will be on the right with respect to torch motion. Therefore, in the cutting of a ring or flange in which the minimum angle is desired on both the inside and outside diameters, the outside would be cut in the clockwise direction, while the inside would be cut counterclockwise (Fig. 11). This change in angle from good side to bad side of the cut is the result of the arc attachment point on the cut surface and the release of energy on the good side before contact with the bad side occurs.

Changing an internal torch part, such as the electrode or gas distributor, can enable those plasma cutting torches that create a gas swirl to change from a clockwise to a counterclockwise swirl direction. This then enables mirror-image cutting when using two torches in a mechanized setup, such as in strip-cutting applications.

**Dross** is the resolidified metal that adheres to the bottom edge of the plasma cut. The concentration of dross will be heavier on the bad side of the cut. The amount of dross that forms is a result of the type of metal being cut, the cutting speed, and the arc current. Dross can be formed from either too high or too low a cutting speed, but there is a “window” between these two extremes in which dross-free cuts can usually be achieved. The dross-free range is greater on stainless steel and aluminum than it is on carbon steel and copper alloys. If dross-free cuts cannot be achieved, then a minimum amount of low-speed dross is more desirable, because it is more easily removed than the high-speed variety.

**Surface Finish.** The cut surface from the plasma arc process is normally rougher than that achieved by oxyfuel cutting on carbon steels, and it is definitely more rough than most machining

processes. In most metals, this roughness usually appears as a ripple along the cut surface. This is partly due to the output waveform of the dc power supply (the smoother the output, the smoother the cut), but it is also determined to an extent by the gases used and the torch design. Water-shielded and water-injection plasma arc cutting provide much smoother cuts than do gas-shielded or conventional plasma techniques. The use of argon-hydrogen as a plasma or a shielding gas will result in smoother cut surfaces on most metals than when using nitrogen plasma or any other gas shield.

**Top-Edge Squareness.** Most metals experience some top-edge rounding when the PAC process is applied. Top-edge rounding is more pronounced on the thinner metals. This rounding is due to a higher heat concentration at the top of the cut and can be minimized by using a gas-shielded PAC process. It can be even better controlled when water-shielded or water-injection plasma arc cutting is used.

**The kerf width** obtained by plasma arc cutting will be greater than that achieved by oxyfuel cutting on carbon steel, but not as great as that obtained by other processes, such as abrasive cutting or arc gouging. Width of kerf

**Fig. 11** Relationship of torch travel direction to the part with clockwise swirl of the orifice gas. With the clockwise swirling plasma gas, the bevel side of the cut is on the left when the operator is looking in the direction of the torch travel. To achieve straight cuts on the inner diameter and the outer diameter of the ring, torch directions must reverse to keep the right side of the cut on the part edge.

**Table 3** Causes of imperfections in plasma arc cuts

Type of imperfection	Cause of imperfection		
	Low-carbon steel	Stainless steel	Aluminum
Top edge rounding	Excessive speed, excessive standoff	Excessive speed, excessive standoff	Seldom occurs
Top edge dross	Excessive standoff, dross easily removed	Excessive standoff, excessive hydrogen	Excessive standoff, dross easily removed
Top side roughness	Seldom occurs	Excessive hydrogen or standoff, insufficient speed	Insufficient hydrogen
Side bevel—positive	Excessive speed, excessive standoff	Excessive speed, excessive standoff	Excessive speed, insufficient hydrogen
Side bevel—negative	Seldom occurs	Seldom occurs	Excessive hydrogen
Top side undercut	Excessive hydrogen	Excessive hydrogen	Insufficient speed, insufficient hydrogen
Bottom side undercut	Seldom occurs	Slight effect at near-optimum conditions	Seldom occurs
Concave surface	Seldom occurs	Excessive hydrogen	Excessive hydrogen, insufficient speed
Convex surface	Excessive speed	Insufficient hydrogen, excessive speed	Seldom occurs
Bottom edge rounding	Excessive speed	Seldom occurs	Seldom occurs
Bottom dross	Excessive hydrogen or speed, insufficient standoff	Insufficient speed, excessive hydrogen	Excessive speed
Bottom side roughness	Insufficient standoff	Seldom occurs	Insufficient hydrogen

is about one to two times the kerf of conventional oxyfuel gas cutting. The range is usually 5 to 10 mm ( $\frac{3}{16}$  to  $\frac{3}{8}$  in.), although some users achieve 0.8 mm ( $\frac{1}{32}$  in.). For thick work metal, width of kerf may exceed 9 mm ( $\frac{3}{8}$  in.). The rule of thumb for estimating the kerf in plasma arc cutting is that its width will be approximately 1.5 to 2 times the tip orifice diameter.

**Heat-Affected Zone.** The high speeds possible with plasma arc cutting result in relatively low heat input to the workpiece. Heat-affected zones are therefore narrow. The HAZ on stainless steel plate 25 mm (1 in.) thick cut at 1270 mm/min (50 in./min) is 0.08 to 0.13 mm (0.003 to 0.005 in.). Sensitization in unstabilized stainless steels is usually avoided, and distortion from cutting is normally avoided.

**Bevel cutting** for weld preparation is an important application of PAC. The intense heat of the process makes it suitable for all types of beveling at a higher efficiency than oxyfuel gas cutting.

## Applications

Plasma arc cutting is used in a variety of industries. Plasma arc cutting can be used to cut any metal. Most applications are for carbon steel, aluminum, and stainless steel. It can be used for stack cutting, plate beveling, shape cutting, and piercing.

In stack cutting, the plates should be clamped together as closely as possible. However, plasma arc cutting can usually tolerate wider gaps between carbon steel plates than can oxyfuel gas cutting. When high plasma arc cutting speeds are used, there is less distortion of the top plate. Several plates of 1.5 to 6 mm ( $\frac{1}{16}$  to  $\frac{1}{4}$  in.) thickness can be economically stack cut.

For shape cutting, PAC torches are used on shape cutting machines similar to those used for oxyfuel gas cutting (see Fig. 6 in the article "Oxyfuel Gas Cutting" in this Volume).

Generally, plasma arc shape cutting machines can operate at higher travel speeds than is possible with oxyfuel gas cutting machines. Because of the fumes and heat produced by the cutting action, water tables are normally used with plasma arc shape cutting machines. The water just touches the bottom of the plate, where it traps the fumes, slag, and dross as they emerge from the bottom of the kerf. It also helps reduce noise.

For smaller systems with output capabilities of 100 A, typical end users include:

- Small job shops that must fabricate specialty and subcontracted items from stainless steel, aluminum, brass, copper, carbon steel, galvanized metal, and other metals
- Manufacturers and installers of ductwork for heating, ventilating, and air conditioning, who must cut galvanized metals
- Manufacturers of food processing and institutional kitchen equipment, who must cut stainless steels
- Automobile manufacturers, auto body repair shops, and dismantlers, who must cut high-strength steels used in unibody construction
- Manufacturers and rebuilders of over-the-road liquid transport trailers used to haul petroleum, chemicals, milk, and fertilizers, who must cut stainless steels and aluminum
- Contractors and maintenance departments that erect and maintain all kinds of plants, including food processing, petroleum, chemical, pulp and paper mills, power plants, and mining operations

For systems with output capabilities greater than 100 A, end users include:

- Large shops that fabricate specialty and subcontracted parts from virtually any metal
- Steel warehouses and service centers that size and shape-cut both ferrous and nonferrous metals, as well as those that size scrap

- Pipe fabricators and piping contractors, who must size, bevel, and make intersection cut-outs on carbon and stainless steel pipe
- Structural fabricators, who must perform high-speed slitting of H and I beams and the sizing and slitting of plate
- Manufacturers of ships, barges, and offshore rig platforms, who must perform plate sizing, pipe cutoff, bulkhead fabrication, and propeller trimming
- Aluminum, steel, and copper mills that size and strip rolled plate and sheet, or that size scrap, or that perform plant equipment maintenance
- Scrap yards that perform high-speed sizing of stainless steel, copper, brass, aluminum, and other metals

## Safety

Operators of PAC equipment should be aware of seven areas of potential hazards that are associated with the process. The proper operation of the equipment and adherence to certain precautions will minimize the risks involved.

**Gases and Fumes.** Potentially hazardous gases associated with the PAC process include ozone, nitrogen dioxide, and phosgene (caused by the breakdown of chlorinated solvents in ultraviolet light). Metal fumes vary with the composition of the metal being cut. Fumes of beryllium, cadmium, cobalt, copper, lead, mercury, silver, vanadium, and several other elements may be hazardous to individuals in the PAC area. Various limits imposed on the levels of gases and fumes in the work area are listed in a handbook published by the Occupational Safety and Health Administration (OSHA) and in the American Welding Society document A6.3-69, "Recommended Safe Practices for Plasma Arc Cutting."

Gases and fumes created by the PAC process can be effectively controlled by properly installed ventilation systems in the work area. Water tables that are used either alone, for surface or underwater cutting, or in conjunction with water-shrouded systems can effectively reduce gases and fumes. Respirators can be used when ventilation systems, and water tables are impractical. Chlorinated solvents and other sources of phosgene gas should be removed from the PAC work area.

**Noise.** The high level of noise associated with some PAC operations (usually high power) can lead to hearing damage. Maximum exposure times to various noise levels are printed in the OSHA handbook. The operator and any other personnel within the vicinity of the PAC operation should wear proper ear protection. Underwater cutting and the use of water-shrouded systems are effective means for reducing noise levels.

**Radiant Energy.** The ultraviolet infrared and visible light from the plasma arc can lead to injury of the eyes and skin. Operators and anyone else in the vicinity of the PAC operation should

Fig. 12 Characteristics of a plasma arc cut

be protected by proper clothing that covers all skin and by welding helmets or shields that contain the proper shaded lens. For high-powered operations, the use of a number 10 (or greater) shaded lens may be required by the operator. If the intensity of the PAC process causes eye discomfort to the operator, a lens with a darker shade should be utilized.

**Electric Shock.** Both the input power to and the output from a PAC system is sufficient to be hazardous if an individual receives a shock from the system. Output voltages in the PAC process usually range from 100 to 200 V dc; typical welding processes run at 20 to 40 V dc. All equipment should be installed and maintained according to the U.S. Standard National Electrical Code and any local standards. All components of a PAC system should be properly earth grounded. System power should be shut off at a wall disconnect before the torch or any other system component is serviced. Any cracked insulators, power leads, or exposed live parts should be corrected immediately. Operators of PAC systems should be insulated from the workpiece and ground, and those who work in wet or damp areas should take precautions to ensure adequate protection from electric shock.

**Fire.** The sparks and the hot molten metal that is blown out of the cut can cause fires. Sparks that result from piercing can travel a considerable distance. All combustibles should be removed from the work area, and a fire extinguisher should be located in the vicinity. Because the pilot arc from a PAC torch is very hot, extra care should be taken to prevent it from contacting clothing and other flammable materials.

**Compressed Gas Cylinders.** High-pressure gas cylinders, which are often used to supply PAC systems, can be hazardous if they are not treated properly. Proper handling requires that valve covers always be in place when transporting cylinders, and that cylinders be secured to stationary objects by chains or lashing straps to prevent them from falling over.

**Explosions.** When hydrogen is used as a plasma or secondary gas, in conjunction with argon, extra care should be taken because it is highly explosive. In some instances, explosions

of hydrogen gas can occur even if hydrogen is not supplied as a portion of the plasma or secondary gas. This is because hydrogen can form when some metals, particularly aluminum, are being cut over a water table, by a reaction between the metal and the water, and by the dissociation of water that is due to the plasma arc. During the cutting operation, the plasma arc can ignite this hydrogen, which will explode if it is confined. Adequate ventilation of these hydrogen pockets is necessary for the safe operation of PAC systems. The water in the water table should not be any deeper than 50.8 mm (2 in.) below the bottom of the metal workpiece support bars. A blower system should be used to flush out all hydrogen from beneath the workpiece.

### Air-Carbon Arc Cutting\*

Air-carbon arc (ACA) cutting removes metal physically, rather than by a chemical (oxidation) process in oxyfuel gas cutting. Gouging or cutting occurs when the intense heat of the arc between the carbon electrode and the workpiece melts part of the workpiece (Fig. 13). A stream of compressed air simultaneously blows through the arc quickly enough to blow the molten material from the kerf or groove. The air must lift the molten metal clear of the arc before the metal solidifies. Because this process does not require oxidation to maintain the cut, it can gouge metals that the oxyfuel cutting process cannot. The metal removal rate depends on the melting rate and efficiency of the air jet in removing the molten metal.

Its most common uses are for weld joint preparation, removal of defective welds, removal of welds and attachments when dismantling tanks and steel structures, and removal of gates, risers, and defects from castings. The low heat input of ACA gouging makes this process ideal for joint preparation and for weld removal on high-strength steels. Base-metal temperatures rise very little, about 80 °C (150 °F) in most applications. Industry has enthusiastically adopted ACA gouging for numerous applications, such as metal fabrication and casting finishing, chemical

and petroleum technology, construction, mining, and general repair and maintenance.

The process is used throughout the world to create consistent grooves requiring little or no additional cleaning on square-butt plate seams to prepare them for welding. The process can then be used to backgouge the seam to sound metal to ensure 100% penetration of the welded joint. If a problem arises during the welding process and an area of the weld does not meet specifications, then the process can be used to remove the defective area without damaging or detrimentally affecting the base metal.

The ACA process is also used in foundries to remove fins and risers from castings. It can then be used to smooth areas that contact the surface to prepare the casting for shipment. The process is flexible, efficient, and cost effective to use on numerous metals, such as carbon steel, stainless steel, and other ferrous alloys; gray, malleable, and ductile iron; aluminum; nickel; copper alloys; and other nonferrous metals.

### Equipment

Typical components of an ACA system are shown in Fig. 14. As in electric arc welding, the ACA process requires an arc of intense heat to develop a molten pool on the workpiece. Compressed air then blows away this molten metal. The process requires a welding power source, an air compressor, a carbon electrode, and a gouging torch. A holder clamps the carbon-graphite electrode in position parallel to an air stream, which exists from orifices in the electrode holder to strike the molten metal immediately behind the arc. The electrode holder contains an air flow control valve, an air hose, and a cable. The cable connects to the welding machine; the air hose connects to a source of compressed air. Cuts or gouges should be made only in the direction of the air flow. The electrode angle will vary, depending on the application. The cutter should maintain the correct arc length to enable air to remove molten metal (Fig. 14b).

**Power Sources.** Constant-voltage direct current with a flat to slightly rising voltage characteristic is best for most ACA cutting applications. Direct current is preferred; copper alloys, however, cut better with alternating current. Table 4 provides data on power sources for ACA cutting and gouging.

Single-phase machines with low open-circuit voltage may not work for ACA gouging. However, any three-phase welding power source of sufficient capacity can be used. The open-circuit voltage should be higher than the required arc voltage to allow for voltage drop in the circuit. Because the arc voltage typically ranges from a low of 35 to a high of 56 V, the open-circuit voltage should be at least 60 V. The actual arc voltage used in the process is governed by arc length and the type of gouging.

Fig. 13 (a) Air-carbon arc cutting action. (b) Manual air-carbon arc cutting

\*Adapted from R.L. Strohl, Air-Carbon Arc Cutting, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p 1172-1177

Direct current, electrode positive (reverse polarity, DCEP) is used with the process, except in special applications discussed later. The electrode should extend, at most, 180 mm (7 in.) from the gouging torch, with the air jet between the electrode and workpiece. A minimum extension of 50 mm (2 in.) should be used. Damage of the torch parts will occur if the electrode sticks out less than 50 mm (2 in.).

**Absorption of Carbon.** Reverse polarity (dc electrode positive) air-carbon arc cutting removes metal faster than does straight polarity (dc electrode negative). However, the dc reverse polarity current carries ionized carbon atoms from the electrode to the base metal, with the potential for increasing the carbon content of the cut surfaces. To minimize this pickup and potential for high hardness, the air stream must be adjusted to ensure removal of all molten metal and the use of proper electrode manipulation techniques is essential.

**Compressed Air.** Ordinary compressed air should be used for ACA gouging. Normal pressures range from 550 to 700 kPa (80 to 100 psi) at the torch. Higher pressures can be used, but they do not remove metal more efficiently. Deep grooves in thick metal require pressures up to 860 kPa (125 psi). A pressure as low as 275 to 415 kPa (40 to 60 psi) may be suitable for light work with a light-duty manual torch. This low level of pressure should not be used with general-duty torches. Air pressure is not critical in ACA cutting; the process requires a sufficient volume of air to ensure a clean, slag-free surface. The amount of air required depends on the type of work (0.08 to 0.9 m<sup>3</sup>/min, or 3 to 33 ft<sup>3</sup>/min, for manual operations and 0.7 to 1.4 m<sup>3</sup>/min, or 25 to 50 ft<sup>3</sup>/min, for mechanized operations).

**Air Supply.** Regardless of the pressure used with manual torches, air hoses should have a minimum inside diameter of 6 mm (1/4 in.) with

no constrictions. Mechanized torches with automatic arc length control should have an air-supply hose with minimum inside diameter of 12 mm (1/2 in.). Attention should be given to the field connections to ensure that this minimum is maintained without severely restricting the air-flow volume. Table 5 gives the consumption rates of compressed air for manual and mechanized torches, as well as compressor power rating for intermittent and continuous use. The compressor receiver tank must be large enough to accommodate the compressor rating.

**Air-carbon arc cutting electrodes** are made from mixtures of carbon and graphite. The three basic types of air-carbon arc cutting electrodes are described below. Cross sections vary; round electrode rods are most common. Electrodes also come in flat, half-round, and special shapes to produce specially designed groove shapes.

**Direct current copper-coated electrodes** are used most frequently because of long life, stable arc characteristics, and groove uniformity. These electrodes are made by mixing carbon and graphite with a binder. When this mixture is baked, it produces dense, homogeneous graphite electrodes of low electrical resistance. These electrodes are then coated with a controlled thickness of copper. The available diameters of these electrodes are 3.2 mm (1/8 in.), 4.0 mm

(5/32 in.), 4.8 mm (3/16 in.), 6.4 mm (1/4 in.), 7.9 mm (5/16 in.), 9.5 mm (3/8 in.), 12.7 mm (1/2 in.), 15.9 mm (5/8 in.), and 19.1 mm (3/4 in.).

Jointed electrodes work without stub loss. They are furnished with a female socket and a matching male tang and are available in diameters of 7.9 mm (5/16 in.), 9.5 mm (3/8 in.), 12.7 mm (1/2 in.), 15.9 mm (5/8 in.), 19.1 mm (3/4 in.), and 25.4 mm (1 in.). Jointed carbons are always used with the male tang pointing up (that is, away from the gouge). This ensures proper joint performance.

Flat, or rectangular, coated electrodes are available in dimensions of 4.0 by 9.5 mm (5/32 by 3/8 in.) and 4.8 by 15.9 mm (3/16 by 5/8 in.). These electrodes are used to make rectangular grooves and to remove weld reinforcements.

**Direct current electrodes** are generally restricted to diameters of less than 9.5 mm (3/8 in.) and are therefore limited in use. During cutting, these electrodes erode more than the coated electrodes. They are manufactured in the same way as the coated electrodes, but without the copper coating. Plain electrodes are available in diameters of 4.0 mm (5/32 in.), 4.8 mm (3/16 in.), 6.4 mm (1/4 in.), 7.9 mm (5/16 in.), and 9.5 mm (3/8 in.).

**Alternating current (ac) coated electrodes** are made from a mixture of carbon, graphite, and

**Table 4 Power sources for air-carbon arc cutting and gouging**

Equipment	Polarity	Use
Variable-voltage motor-generator, resistor, and resistor grid	Direct current	All electrode sizes
Constant-voltage motor generator, rectifier	Direct current	Electrodes > 1/4 in. in diameter
Transformer	Alternating current	Alternating current electrodes only
Rectifier	Alternating current, direct current	Direct current from three-phase transformer only; single-phase source not recommended. Use alternating current with alternating current electrodes only.

**Fig. 14** Carbon-air arc system. (a) Arrangement of basic components. (b) Details of carbon-air cutting torch

a special binder. Rare-earth materials are added to ensure arc stabilization when using alternating current. These electrodes, coated with copper, are available in diameters of 4.8 mm ( $3/16$  in.), 6.4 mm ( $1/4$  in.), 9.5 mm ( $3/8$  in.), and 13 mm ( $1/2$  in.).

A **manual gouging torch** is shown in Fig. 15. The electrode is held in a swivel head that contains one or more air holes, so that the air jet stays aligned with the electrode, regardless of the angle of the electrode to the gouging torch. Torches with two heads (that is, the air jet is on two sides of the electrode) or with a fixed angle between the electrode and the holder are better for certain applications, such as removing pads and risers from large castings (pad washing).

Manual torches are usually air cooled. In high-current applications, water-cooled cable assemblies can be used with heavy-duty torches.

**Control of Automatic Gouging Torches.** There are two methods of controlling automatic ACA gouging torches. Either method can make grooves of consistent depth to a tolerance of  $\pm 0.64$  mm ( $\pm 0.025$  in.). These automatic units are used to achieve high-quality gouges and to increase production (Fig. 16).

The *amperage-controlled method* maintains the arc current by amperage signals through solid-state controls. This method controls the electrode feed speed, which maintains the preset

amperage. It is run with constant-voltage power sources only.

A *voltage-controlled method* maintains arc length by voltage signals through solid-state electronic controls. This method controls the electrode feed speed, which maintains the preset voltage. It can run with constant-current power sources.

### Operating Techniques

The angle of the electrode, speed of cut, and amount of current determine depth and contour of the cut or groove. The electrode is held at an angle, and an arc is struck between the end of the electrode and the work metal. The electrode is then pushed forward. Data on groove depth, electrode size, current, and travel speed for air-carbon arc gouging is available from various equipment manufacturers.

For through-cutting, the electrode is placed at a steeper angle, almost vertically inclined. Plate thicknesses greater than 13 mm ( $1/2$  in.) may require multiple passes.

Grooves as deep as 25 mm (1 in.) can be made in a single pass. A steep angle, approaching that used for through-cutting, and rapid advance produce a deep, narrow groove; a flatter angle and slower advance produce a wide, shallow groove. Electrode diameter directly influences groove width. Operators should use a wash or

weave action to remove excess metal such as risers and pad stubs, or in surfacing. Smoothness of the gouged or cut surface depends on the stability of electrode positioning, as well as on the steadiness of the electrode as it advances during the cutting operation. Mechanized gouging, with the electrode and holder traveling in a carriage on a track, produces smoother surfaces five times faster than does manual work.

**Gouging with Manual Torches.** As shown in Fig. 14(b), the electrode should be gripped so that a maximum of 180 mm (7 in.) extends from the torch. For aluminum, this extension should be 75 mm (3 in.). Table 6 shows suggested currents for the different electrode types and sizes.

The air jet should be turned on before striking the arc, and the torch should be held as shown in Fig. 17. The electrode should slope back from the direction of travel, with the air jet behind the electrode. During gouging, the air jet sweeps beneath the electrode end and removes all molten metal. The arc can be struck by lightly touching the electrode to the workpiece. The electrode should not be drawn back once the arc is struck.

Gouging is different from arc welding in that metal is removed, rather than deposited. A short arc should be maintained in the direction of cut by working fast enough to keep up with metal removal. Steadiness of movement controls the smoothness of the resulting cut.

Vertical gouging should be conducted downhill, permitting gravity to help remove the molten metal. Although vertical gouging can

**Table 5 Recommended minimum air supply requirements for air-carbon arc cutting**

Type of torch	Air pressure(a)		Air consumption		Recommended compressor rating				ASME receiver size

be accomplished uphill, it is difficult. Horizontal gouging can be done either to the right or to the left, but always with forehand gouging.

The air jet should always be positioned under the electrode. When gouging in the overhead position, the electrode and torch should be held to prevent molten metal from dripping on the glove of the operator. The depth of the groove is controlled by the travel speed. Grooves up to 25 mm (1 in.) deep can be made. However, the deeper the groove, the more experienced the operator needs to be. Slow travel speeds will produce a deep groove. Fast speeds will produce a shallow groove. The width of the groove is determined by the size of the electrode used. The groove is usually about 3.2 mm ( $\frac{1}{8}$  in.) wider than the diameter of the electrode. A wider groove can be made with a small electrode that is oscillated in either a circular or weave motion. When gouging, a push angle that is  $35^\circ$  from the surface of the workpiece should be used for most applications. A steady rest will ensure a smoothly gouged surface, especially in the overhead position. Proper travel speed depends on electrode size, the base metal being used, amperage, and air pressure. The proper speed, which produces a smooth hissing sound, will result in a good gouge.

**The severing technique** is like gouging, except that the operator holds the electrode at a steeper angle that is between  $70^\circ$  and  $80^\circ$  to the workpiece surface. When cutting thick, non-ferrous metals, the electrode should be held perpendicular to the workpiece, with the air jet favoring the desired side. With the electrode in this position, the operator can sever the metal by moving the arc up and down using a sawing motion.

**Washing.** When using the ACA process to remove metal from large areas (for example, surfacing metal or riser pads on castings), the operator should position the electrode as shown in Fig. 18. The electrode should weave from side to side while it is being pushed forward at the depth desired. In the pad-washing operation, an angle that is  $15$  to  $70^\circ$  to the workpiece should

be used. The  $15^\circ$  angle is used for light finishing passes, whereas steeper angles allow deeper rough gouging with greater ease.

Gouging torches with fixed-angle heads that hold the electrode at the correct angle are well-suited for this application. When other types of torches are used, the air jet should be kept behind the electrode. Operator steadiness determines the smoothness of the surface produced.

**Beveling.** In one beveling method that is used for thick plates, the electrode should be held with a travel angle of  $90^\circ$  and a work angle that is equal to the bevel angle. The air jet should be positioned between the electrode and the workpiece. A second method, usually used for thin plates, requires that the torch be held parallel to the edge being beveled. Its position should equal the bevel angle. The air jet should be positioned between the electrode and the workpiece surface.

### Equipment Selection

**Gouging torches** are selected for the specific application. They range from light-duty sizes appropriate for farm and body shop applications to extra-heavy-duty torches that are best suited to foundry applications.

**General-purpose torches** are available in four duty levels. Light-duty torches accept round electrodes that range from 3.2 to 6.5 mm ( $\frac{1}{8}$  to  $\frac{1}{4}$  in.) and 9.5 mm ( $\frac{3}{8}$  in.) flat electrodes. Their maximum current level is 450 A. Medium-duty torches accept round electrodes that range from 3.97 to 9.5 mm ( $\frac{5}{32}$  to  $\frac{3}{8}$  in.) and 9.5 mm ( $\frac{3}{8}$  in.) flat electrodes. Their maximum current level is 600 A. Heavy-duty torches accept round electrodes that range from 3.97 to 12.7 mm ( $\frac{5}{32}$  to  $\frac{1}{2}$  in.) and flat electrodes of 9.5 or 15.9 mm ( $\frac{3}{8}$  or  $\frac{5}{8}$  in.). Their maximum current level is 1000 A. Extra-heavy-duty torches accept round electrodes that range from 3.97 to 15.9 mm ( $\frac{5}{32}$

to  $\frac{5}{8}$  in.) and flat electrodes of 9.5 or 15.9 mm ( $\frac{3}{8}$  or  $\frac{5}{8}$  in.). Their maximum current level is 1250 A.

**Foundry heavy-duty torches** are appropriate for general foundry work and heavy-duty fabrication. They are limited to 1600 A when used with air-cooled cables and 2000 A when used with water-cooled cables.

**Automated gouging torches** are used for edge preparations and backgouging, as well as high-quality and high-productivity applications. Jointed carbon electrodes ranging from 7.9 to 19.1 mm ( $\frac{5}{16}$  to  $\frac{3}{4}$  in.) are accepted.

**Power Sources.** Any three-phase welding power source with enough capacity can be used for the ACA gouging process if the open-circuit voltage is high enough to allow for a voltage drop in the circuit. Some constant-voltage power sources with drooping characteristics require a very high open-circuit voltage to run ACA gouging equipment. Mechanized gouging and other applications that require maximum arc time should utilize a power source with a 100% duty cycle for the required amperage.

A dc constant-current power source motor generator, rectifier, or resistor grid unit is preferred for use with all electrode sizes. A dc constant-voltage power source motor generator or rectifier is usable only for 7.9 mm ( $\frac{5}{16}$  in.) diam and larger electrodes. It may cause carbon deposits when used with small electrodes, and it is not suitable for automatic torches with voltage control only. An ac constant-current power source (transformer) is recommended for ac electrodes only. With ac/dc transformer rectifiers, the direct current should be supplied by a three-phase source, because single-phase sources give unsatisfactory arc characteristics. Alternating current output from ac/dc units is satisfactory, if ac electrodes are used.

**Automatic systems** are often used in modern fabrication facilities. These systems offer a high-quality, high-productivity alternative to manual

Fig. 17 Flat gouging position

Fig. 18 Pad-washing technique. The torch remains parallel to the workpiece, and a weaving motion is used forward across the width of the area being cleaned. The electrode-to-workpiece angle should be from  $15$  to  $70^\circ$ . The more shallow the angle, the smoother the finish; the  $70^\circ$  angle is used mainly on cast iron.

gouging. Two types of systems can be considered. Both operate on a signal from the arc to control the gouging.

**Dual-Signal System.** Either constant-current or constant-voltage power supplies can be used with this type of automatic system. When the system uses constant current, the arc length is maintained through a voltage-signal system. A predetermined voltage setting is set on the system controller, which then advances or retracts the electrode through a stepping motor to maintain the arc length. With a constant-voltage power source, amperage sensing controls the feeding or retracting of the electrode to maintain the right arc current.

**The single-signal system,** like the dual-signal system, maintains arc length through voltage signal. However, it will not operate with an amperage signal. This type of system only operates with a constant-current power source.

**Advantages.** Automatic ACA systems ensure better productivity and quality. The systems can perform out-of-position gouging. They perform well when making long gouges in flat workpieces using a moving gouging apparatus and when making circular gouges in pipes and tanks using stationary gouging apparatus. They produce an even U-shaped groove and can control the depth of the groove to within  $\pm 0.64$  mm ( $\pm 0.025$  in.). Table 7 shows typical operating information for U-shaped grooves.

**Vacuum gouging** represents a new variation of gouging that was developed in the late 1980s. This process replaces the air jet that is used to

evacuate the molten slag from the groove area with a high-volume vacuum that not only captures the slag and fume associated with the gouging process, but also reduces the noise level created when performing the gouging process.

The vacuum gouging process utilizes a specially designed nozzle that attaches to an automatic gouging head. By water cooling the nozzle and the attached vacuum hose, the slag and fume from the gouging process are pulled by the vacuum into a capture drum. The slag is knocked into the bottom of the catch tank, which is partially filled with water, and the fume is caught in a filter before the air is exhausted from the vacuum. Currently, this new vacuum system is limited to automated gouging operations on flat plate or pressure vessel circumferential seams.

### Important Process Variables

Like any thermal-cutting process, the ACA process is sensitive to variables in operation. These variables can cause changes in the finished gouge that range from being undetectable to being unacceptable.

**Electrode diameter and type** are variables that determine the groove size, as well as productivity, groove quality, and metal-removal rates. The width of the groove will be about 3.2 mm ( $1/8$  in.) wider than the diameter of the electrode. The choice of a proper electrode can be based on the size of the desired groove. Available power will dictate the outer limit. For example, a 13 mm ( $1/2$  in.) wide, 6.4 mm ( $1/4$  in.) deep groove that is 254 mm (10 in.) long could be made manually in two passes using a 6.4 mm ( $1/4$  in.) diam electrode, or in one pass using a 9.5 mm ( $3/8$  in.) diam electrode. In the first case, the best gouging rate would be 254 mm/min (10 in./min), divided by 2, or 125 mm/min (5 in./min). The travel speed of the second case (one pass) is 430 mm/min (17 in./min).

The 9.5 mm ( $3/8$  in.) diam electrode increases the gouging rate by 200%, which could offset the additional cost of the electrode. Automatic systems increase the productivity rate even further, through finite control of the arc voltage.

**The gouging amperage** is the melting force of the process. It is affected by electrode size. If the amperage were set too low for the electrode size, then the melting rate of the base metal would be inadequate and free-carbon deposits would occur. Although the base metal would melt, a setting that is too high would rapidly deteriorate the electrode while reducing the metal removed per electrode. Too high a setting can also substantially reduce torch life.

**Voltage** is the pressure, or arc force, that enables the current to flow across the arc gap. The ACA process often requires a higher voltage than do most welding processes. To ensure proper operation, a power source with a high enough open-circuit voltage to maintain a 28 V operating minimum should be used. Inadequate voltage can create a sputtering arc or it can

prevent arc establishment, resulting in uneven grooves and, probably, free-carbon deposits that would require excessive grinding to remove.

**Adequate air pressure and flow rate** are required for the adequate removal of molten metal by the air jet. Air volume is as important as air pressure. Pressure is the speed of the air that moves the molten metal from the groove. If there is an inadequate volume of air to lift the molten material out of the groove, then it cannot be removed by the pressure or velocity. The result is excessive slag adhesion and unnecessary grinding to clean up the groove.

**Travel speed** affects the depth of the gouge and the quality of the groove. The faster the travel speed of an electrode, the shallower the gouge. A smaller electrode can be used if the travel speed is too fast for the comfort of the operator, or automatic gouging can be used. A groove that is too deep for the diameter of the electrode results in a poor-quality groove that requires much grinding.

**The electrode push angle** can vary somewhat. When gouging manually, a steeper angle tends to give a more V-shaped groove. When gouging automatically, a steeper angle gives a slightly deeper groove at the same travel speed.

**Base Metals.** The gouging procedures that are recommended for specific base metals are:

- For carbon steel and low-alloy steel, such as ASTM A 514 and A 517, use dc electrodes with DCEP. Although ac electrodes with an ac transformer can be used, their efficiency is half that of dc electrodes.
- For stainless steel, the same guidelines apply as for carbon steel.
- For cast iron, including malleable and ductile (nodular) forms, use 13 mm ( $1/2$  in.) diam or larger electrodes at the highest rated amperage. Special techniques are needed when gouging these metals. The push angle should be at least  $70^\circ$  off the workpiece, and the depth of the cut should not exceed 13 mm ( $1/2$  in.) per pass.
- For copper alloys (copper content  $\leq 60\%$ ), use dc electrodes with direct current electrode negative (DCEN) at the maximum amperage rating of the electrode.
- For copper alloys (copper content  $> 60\%$  or large workpiece), use dc electrodes with DCEN at the maximum amperage rating of the electrode, or use ac electrodes with alternating current.
- For aluminum bronze and aluminum-nickel-bronze (special naval propeller alloys), use dc electrodes with DCEN.
- For nickel alloys (nickel content  $> 80\%$  of mass), use ac electrodes with alternating current.
- For nickel alloys (nickel content  $< 80\%$  of mass), use dc electrodes with DCEP.
- For magnesium alloys, use dc electrodes with DCEP and wire-brush the groove before welding.
- For aluminum alloys, use dc electrodes with DCEP and wire-brush the groove with

**Table 7 Automatic air-carbon arc U-shaped groove operating data(a)**

Electrode diameter		Desired depth		dc current, A	Travel speed	
mm	in.	mm	in.		mm/min	in./min
7.9	$5/16$	3.2	$1/8$	400	1651	65
		4.8	$3/16$	400	1143	45
		6.4	$1/4$	450	914	36
		7.9	$5/16$	450	838	33

12.7	$1/2$	3.2	$1/8$	850	2438	96
		6.4	$1/4$	850	1448	57
		9.5	$3/8$	850	889	35
		12.7	$1/2$	850	610	24
		19.1	$3/4$	850	445	17.5
15.9	$5/8$	6.4	$1/4$	1250	1829	72
		9.5	$3/8$	1250	1219	48
		12.7	$1/2$	1250	940	37
		15.9	$5/8$	1250	762	30
		23.8	$15/16$	1250	495	19.5
19.1	$3/4$	6.4	$1/4$	1400	1829	72
		9.5	$3/8$	1400	1068	42
		12.7	$1/2$	1400	865	34
		15.9	$5/8$	1400	687	27
		19.1	$3/4$	1400	560	22
		28.6	$1 1/8$	1400	330	13

Note: If a groove depth greater than 1.5 times the diameter of the electrode being used is desired, then the groove should be made in two or more passes. (a) Based on laboratory conditions; information should be used as a guide and adjusted for field variance as required

stainless brushes before welding. Electrode extension (length of electrode between torch and work) should not exceed 75 mm (3 in.). Direct current electrodes with DCEN can also be used.

- For titanium, zirconium, hafnium, and their alloys, there are no current procedures. If these metals are prepared for welding using the ACA process, then the groove should be cleaned before welding. These metals can be cut for remelting. In cases where preheat is required for welding, a similar preheat should be used for gouging.

### Effects on Base Metal

Metallurgically, the base metal is not affected by the carbon particles being carried toward it from the electrode, because it remains solid and the atoms are very tightly packed. However, because the material being removed is molten, the atoms are loosely spread. This material, usually referred to as slag, easily absorbs the carbon particles.

If the ACA process is properly used, no surface carburization will occur. Due to the rapid quenching effect of the air used to remove the metal, the HAZ will undergo hardening. The HAZ for ACA is typically 2.5 mm (0.10 in.) or less in thickness. This HAZ hardening must be considered when a finish machining operation follows the gouging process, especially when working on high-carbon steels. Some materials (for example, nickel) will undergo surface cracking when gouged. These conditions should be considered when choosing the parameters for any required machining operations.

When the ACA process is used under improper conditions, this molten carburized metal may be left on the workpiece surface. Its color is a dull gray-black, in contrast to the bright blue of the properly made groove. Inadequate air flow may leave small pools of carburized metal in the bottom of the groove. Irregular electrode travel, especially in a manual operation, may cause ripples in the groove wall that trap the carburized metal. Finally, an improper electrode push angle may cause small beads of carburized metal to remain on the edge of the groove.

Copper from copper-coated electrodes does not transfer to the cut surface in base metal, unless the process is improperly used.

Carburized metal can be removed from a cut surface by grinding, but the necessity to do so can be prevented by gouging properly in the right condition.

When compared with oxyfuel cutting, the ACA process requires less heat input. Therefore, a workpiece that is gouged or cut by the ACA process is less distorted. The machining of low-carbon and nonhardenable steel is not affected by the ACA process. However, when used on cast iron and high-carbon steels, this process may cause enough hardening to make the cut surface tough to machine. Still, because the hardened zone is shallow (approximately 0.15 mm, or

0.006 in.), a cutting tool can penetrate it to remove the hardened surface.

### Safety and Health

Safe practices in welding and cutting processes are described in ANSI Z49.1, "Safety in Welding and Cutting," and ANSI Z49.2, "Fire Prevention in Use of Welding and Cutting Processes" (American National Standards Institute). The operators of the ACA process and their supervisors should adhere to the practices discussed in these documents.

**Electrodes.** An electrode that carries electric current will arc if it touches the workpiece or any grounded metal object. Proper handling of the torch and electrode will prevent accidental arcing. Electrodes should always be used within their proper amperage range in order to effectively remove metal and to avoid damage to the torch. Carbon electrodes should be kept dry. Damp electrodes should be baked for 10 h at 150 °C (300 °F). Wet electrodes may shatter.

**Torches.** Oxygen should never be used in an air-carbon arc torch. Neither the torch nor the electrode should ever be immersed in water. All electrical connections should be wrench tight before the torches are used.

**Electrical Power.** The ACA process uses electric energy from a welding power source. The same safety precautions should be used as when welding. An operator should never stand in water while using ACA equipment, and the torches and electrodes should never be cooled by water. To prevent accidental arcing, partially used electrodes should be removed from torches when work is interrupted.

**Personal Protective Equipment and Clothing.** A No. 12 shade-filter lens should be used for eye protection against arc radiation. When conducting heavy metal removal operations with large electrodes, a No. 14 shade-filter lens or an equivalent combination of filter lenses provides the best protection. Flash goggles should be used, especially when two or more welders are working in the same area. Proper protective clothing must be worn to provide enough protection from the infrared and ultraviolet radiations of the arc. Leather aprons, sleeves, leggings, and so on should be used for out-of-position gouging or for heavy metal removal operations with large electrodes. Ear protection is recommended when noise exceeds permissible levels.

**Fire and Burn Hazards.** The ACA process may cause fire. All flammable materials should be removed from the work area. Booths, metal screens, and other deflectors should be placed to catch the hot metal and particle spray ejected by the compressed air stream. Protective clothing should be used to prevent burns caused by contact with hot metal or electrodes. Out-of-position or heavy metal removal operations require that many precautions be taken.

**Ventilation Hazards.** The fumes from the ACA process can be harmful. Ventilation and/or an exhaust around the arc is necessary. When

using gouging torches, the operator should keep his head away from the fumes. Protective-breathing or air-circulation gear may be needed.

### Other Electric Arc Cutting Methods

**Exo-Process.** A relatively new electric arc cutting process, called the Exo-Process, has been developed. Similar to flux-cored processes, it uses a consumable tubular electrode and a specially designed gun that feeds high-speed compressed air to the arc (Fig. 19). The air flow functions to push molten metal from the gouge cavity, to constrict the arc for more precise control, and to cool the electrode. The system can be adapted to conventional gas metal arc welding equipment (it requires a direct current constant-voltage power source—150 A minimum—and a conventional wire feeder).

The velocity of the air flow at the arc is the key factor for straight cutting. A 1.5 mm ( $1/16$  in.) wire size can cut up to 6 mm ( $1/4$  in.) thick carbon steel. Speed and edge cut quality on most commercial metals and alloys is good, particularly for sheet metal thicknesses. Gouge quality on carbon steels is also good. The process would be well suited for automated equipment, in that high travel speeds may be attained. An obvious benefit of the process is that it can be mounted on a gas metal arc dual-wire feed system to provide the operator with a multifunctional welding and cutting unit.

**Oxygen arc cutting** uses a flux-covered tubular steel electrode. The covering insulates the electrode from arcing between it and the sides of the cut. The arc raises the work material to combustion temperature; the oxygen stream burns the material away. Oxidation, or combustion, liberates additional heat to support continuing combustion of sidewall material as the cut progresses. The electric arc supplies the preheat necessary to obtain and maintain ignition at the point where the oxygen jet strikes the

Fig. 19 The Exo-Process for gouging

Fig. 20 Components of an oxygen arc electrode

surface of the work. The process finds greatest use in underwater cutting.

Oxygen arc cutting has been used effectively for cutting steels, stainless steels, cast iron, and nonferrous metals in any position. When cutting oxidation-resistant metals, melting action occurs. The covering on the electrode acts as a flux; it functions in a manner similar to that of powdered flux or powdered metal injected into the gas flame in the flux-injection method of oxyfuel gas cutting of stainless steel.

Oxygen arc cutting uses direct or alternating current, although DCEN, straight polarity, is preferred. The electrode and the electrode holder convey the electric current and oxygen to the

arc. Electrode holders must be fully insulated; underwater cutting requires a flashback arrester, and the electrode must have a watertight plastic coating. Components of an oxygen arc electrode are shown in Fig. 20.

**Seldom-Used Electric Arc Cutting Methods.** The four electric arc cutting processes described in this section either are almost obsolete or have never been used extensively. However, these processes are sometimes used for highly specialized applications or when equipment for more suitable methods is not available.

*Carbon arc cutting* is one of the oldest electric arc cutting methods. This process uses the heat generated by the carbon arc to melt metal progressively to produce a kerf. The melted metal is removed from the cut by gravity or by the force of the arc, or by both.

The use of carbon arc cutting is limited to cutting up of scrap and dismantling of structural steel assemblies.

*Shielded Metal Arc Cutting.* Metal can be cut by a shielded metal arc, using flux-covered stick electrodes. The molten metal is removed from the cut by gravity or by the force of the arc, or both.

Shielded metal arc cutting is most commonly used for removing gates and risers from castings and for cutting up scrap. The process can also be used for underwater cutting with specially processed (waterproof) electrodes.

*Gas Metal Arc Cutting (MIG).* In this process, heat is obtained from an electric arc formed

between a continuously fed wire and the work metal. The molten metal is continuously blown from the kerf by the shielding gas. The process is used mainly on stainless steel and aluminum, although other metals can be cut by this method.

Gas metal arc cutting is most often used in fabricating shops where gas metal arc welding is done, as the same equipment can be used for both cutting and welding. Gas metal arc cutting is limited in application, because the rate of wire consumption is high, and the thickness of sections that can be cut is limited to about 1½ in. for stainless steel and about 3 in. for aluminum.

*Gas tungsten arc cutting (TIG)* is similar to gas tungsten arc welding, except that higher amperages and voltages are used. The same basic circuit and similar shielding gases are used for both processes.

Although TIG can be used for cutting most ferrous and nonferrous metals, it is largely confined to the cutting of stainless steel and aluminum ½ in. or less in thickness. The quality of the cut is usually good enough to permit welding without machining the cut surfaces.

# Laser Cutting

INDUSTRIAL LASERS are being used in numerous materials processing applications. They can weld microswitches and auto transmission gears, scribe and machine ceramic substrates, and drill jet engine turbine blades and baby bottle nipples. They are also used in heat treating, cladding, ablating, and marking. However, cutting represents their largest single application, primarily two-axis profiling of sheet goods that may otherwise have been blanked out by punch press or fabricated by hand after laborious layout of the pattern.

The versatility of the laser in cutting operations is responsible for its widespread use. The same laser can be used to cut men's suits, newspapers, circuit boards, motorcycle fenders, circular saw blades, stainless steel auto exhaust tubing, and 13 mm (0.5 in.) thick alloy steel for aircraft disc brakes.

Its flexibility makes the laser an ideal tool for prototype or production work. Because laser cutting is a noncontact process, no tool wear occurs. Laser systems can cut intricate parts with accuracies of  $\pm 0.025$  mm ( $\pm 0.001$  in.) and with surface finishes better than  $1.3\text{ }\mu\text{m}$  ( $50\text{ }\mu\text{in.}$ ) for some steels, and better than  $0.50\text{ }\mu\text{m}$  ( $20\text{ }\mu\text{in.}$ ) for some nonmetals. Because laser cutting gives a clean edge, secondary operations such as deburring can be reduced or eliminated.

Laser cutting of metal typically falls within 9.5 mm (0.375 in.) and thinner, although CO<sub>2</sub> lasers are now competitive with plasma arc cutting for metal thicknesses of 13 mm (0.500 in.) and greater. The principal factor in the use of laser metal cutting is manufacturing methodology. Laser cutting is ideal for batch processes, just-in-time, or low to medium-volume production. Most laser-cutting work is performed on generic or multipurpose materials handling systems, as opposed to dedicated automation-controlled systems. Technical features of laser cutting are compared with other methods of cutting in Table 1 (Ref 1).

## Definition of a Laser

The word *laser* is an acronym for light amplification by stimulated emission of radiation. There are essentially three components that are necessary for lasing action. There must be an active media that can be excited, a method of

exciting the media, such as an electrical discharge between an anode and cathode, and a resonator.

The molecules of the active media must be excited in order to stimulate the emission of radiant energy or light. As the molecules are charged to a higher energy state, they excite their electrons into a higher energy level. Because unstable electrons seek their lowest energy state, they release this added energy as light particles, known as photons.

The resonator consists of two parallel mirrors that reflect light particles between them, thereby amplifying the stimulated emission of light. Of the two mirrors in the resonator, the rear mirror is 100% reflective, while the front, or output, mirror is typically only 50% reflective and therefore 50% transmissive. The percentage of light that is transmitted through the front mirror is commonly known as the laser beam. It is this parallel, monochromatic, intense beam of light particles that is used for materials processing. The percentage of light remaining inside the resonator is necessary to maintain the continuous stimulated emission of photons.

## Laser Types

Generally, there is a clear-cut reason for using one type of laser over another. Carbon dioxide (CO<sub>2</sub>) lasers are capable of delivering much higher average power than neodymium: yttrium-aluminum-garnet (Nd:YAG) lasers. As such, CO<sub>2</sub> lasers can cut faster and produce deeper weld penetration than Nd:YAG lasers. Pulsed Nd:YAG lasers develop a high pulse energy that allows percussion drilling and the cutting of metals at angles and thicknesses not possible with CO<sub>2</sub> lasers. There are some applications—spot welding and hole cutting, for example—where either laser type can provide acceptable results at comparable speeds. Capabilities and operating ranges for CO<sub>2</sub> and Nd:YAG lasers are shown in Tables 2 and 3.

The CO<sub>2</sub> laser and the Nd:YAG laser are by far the most commonly used materials-processing lasers. The CO<sub>2</sub> laser relies on a gas mixture of CO<sub>2</sub>, helium (He), and nitrogen (N) as its active media. It usually uses an electrical discharge between an anode and cathode as the method of

media excitation, and the standard two-mirror resonator. The CO<sub>2</sub> laser produces a wavelength of 10.6  $\mu\text{m}$  (420  $\mu\text{in.}$ ), which is invisible to the human eye. Visible light falls between 0.4 and 0.7  $\mu\text{m}$  (15 and 28  $\mu\text{in.}$ ). Although practical materials-processing lasers have powers ranging from 150 W to 8 kW, CO<sub>2</sub> lasers have been built with powers above 25 kW. Most lasers used for cutting have powers that range from 150 W to 3 kW. Figure 1 shows a typical CO<sub>2</sub> gas laser design.

Cutting with lasers is accomplished with CO<sub>2</sub> and Nd:YAG lasers. More often, cutting is done with CO<sub>2</sub> lasers because of the faster cutting rates. Typical cutting rates for a 1250 W CO<sub>2</sub> laser are illustrated in Fig. 2. Process variables (Ref 2) in laser cutting are described as follows.

**Average power** for cutting with a continuous-wave CO<sub>2</sub> laser is typically 250 to 5000 W. In the pulsed mode, lower average powers can cut metal because of higher peak instantaneous powers. The power ranges for cutting metal in the pulsed mode range from less than 100 to 2000 W for CO<sub>2</sub> lasers. Cutting with Nd:YAG lasers is accomplished with a power range of less than 100 to more than 400 W.

**Pulse length** is selected to optimize the quality of the cut surface. Shorter pulse lengths (<0.75 ms) are used for the intricate cutting of thin metals. Shorter pulse lengths may limit the maximum energy achievable in a single pulse. Longer pulse lengths (up to 2 ms) provide greater pulse energies, allowing thicker metals to be cut. Similar pulse lengths would be used for both CO<sub>2</sub> and Nd:YAG lasers.

**Pulse frequency** is adjusted to give the maximum cutting speed for the quality required. In general, higher frequencies are used to cut thinner metals. For CO<sub>2</sub> lasers, higher frequencies range from 200 to 500 Hz. In Nd:YAG lasers, higher frequencies range from 30 to 100 Hz. Lower frequencies are used to cut thicker metal sections.

**Pulse energy** needed in cutting is related to material thickness. As metal thickness increases, greater pulse energy is required. In practice, CO<sub>2</sub> lasers deliver maximum pulse energies up to 2 J at longer pulse lengths and lower pulse frequencies. Nd:YAG lasers can produce much higher pulse energies up to 80 J, with pulse frequency limited by the maximum power rating of the laser.

**Lens choice** is based on metal thickness, composition, and quality requirements and on beam diameter. Wider kerf widths are obtained by using longer focal-length lenses, and some materials, such as aluminum, require a larger kerf width for good results. The following guidelines are for beam diameters from 13 to 25 mm (0.5 to 1 in.).

For CO<sub>2</sub> lasers, a general rule is to use a 65 mm (2.5 in.) focal length for cutting metals up to 6 mm (0.25 in.) thick. A 125 mm (5 in.) focal-length lens can be used for metals from 5 to 15.8 mm (0.2 to 0.625 in.) thick. A 190 or 250 mm (7.5 or 10 in.) lens can be used for materials thicker than 13 mm (0.5 in.).

Typical lenses for Nd:YAG lasers have focal lengths of 100 mm (4 in.) for metals thinner than 3 mm (0.125 in.). For cutting metals up to 25 mm (1 in.), the focal lengths range from 150 to 250 mm (6 to 10 in.). Thicker metals require even longer focal lengths.

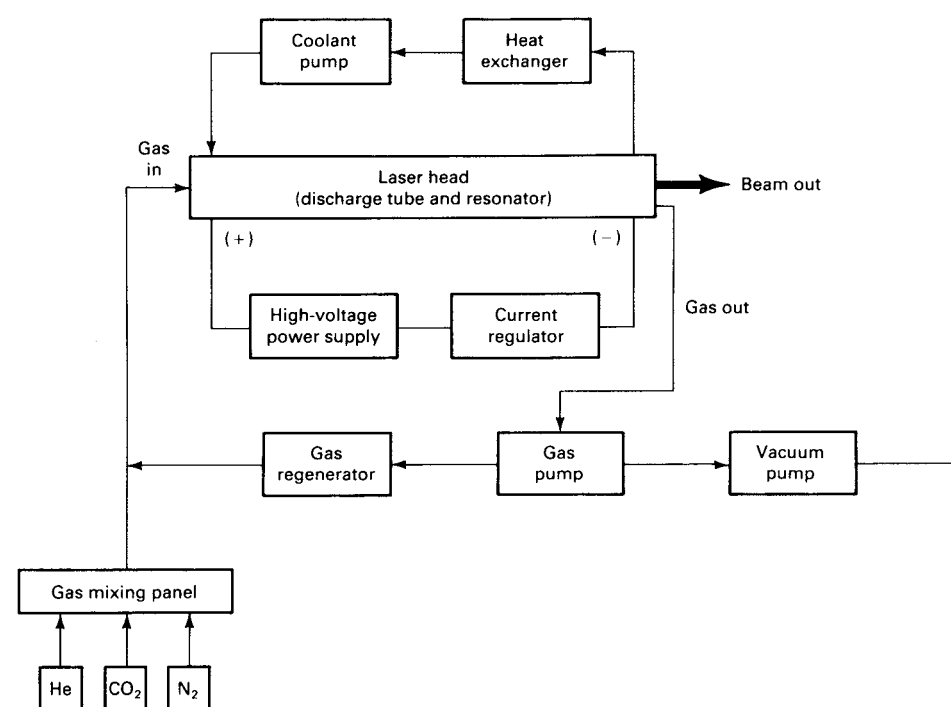

**Gas jets** provide a coaxial, columnar flow of gas through the cut slot to remove molten metal. The gas type can be oxygen, inert gas, or air, depending on material type and quality requirements. Oxygen is most commonly used for cutting steels. When an oxide-free surface is desired, an inert gas, such as helium, is used.

Gas pressures for oxygen range from 100 to 350 kPa (15 to 50 psi), while pressures for inert gases range from 200 to 620 kPa (30 to 90 psi). Typical nozzle orifices range from 0.75 to 2.5 mm (0.030 to 0.100 in.). Nozzle standoff,

**Fig. 2** Cutting rates for 1250 W CO<sub>2</sub> laser

depending on laser type, nozzle design, and gas flow rates, varies from 0 to 1.5 mm (0.0 to 0.06 in.) for CO<sub>2</sub> lasers and up to 5 mm (0.200 in.) for Nd:YAG lasers. Nozzle standoff and gas pressure to a large degree determine the quality of the cut. Using a CO<sub>2</sub> laser, a clean cut (oxide free and dross free) can be achieved in thinner sections of metals such as stainless steel, aluminum, or titanium when using inert coaxial gas at 620 kPa (90 psi) with minimum nozzle standoff.

## CO<sub>2</sub> Lasers

There are three basic types of CO<sub>2</sub> gas lasers: slow axial flow, transverse flow, and fast axial flow.

**The slow axial flow laser** is an older, proven design that has excellent mode, stability, and pulsing capabilities. They are available with powers up to approximately 800 W, allowing them to cut steels up to 6.5 mm (0.25 in.) thick. Figure 3 shows the typical design theory of a slow axial flow laser. The lasing action occurs by injecting laser gas at a pressure of approximately 2.7 kPa (20 torr) into an evacuated glass tube. The tube has a rear mirror and an output coupler at either end. A high-voltage glow discharge is then passed down the tube between an anode and cathode, causing lasing to occur. This design, which can only create 70 W/m (20 W/ft) of tube length, requires a long resonator cavity to produce high power levels.

**The transverse-flow laser** was developed in response to the size versus power limitations of the slow axial flow laser. Transverse-flow laser design allows power to be generated to approximately 25 kW. The transverse laser accomplishes this by using a tangential blower to move a high volume of laser gas transversely across the anode-cathode electrical path, as shown in Fig. 4. The basis of this design is that power is directly related to the volume of laser gas that is excited at any one time. The drawbacks are that these lasers cannot be electronically pulsed for cutting very intricate geometries, and the beam quality, or mode, is not ideal for high-quality cutting applications.

**The fast axial flow laser** is the newest CO<sub>2</sub> type. It combines the high power of the transverse-flow laser with the beam quality and some of the pulsing capabilities of the slow axial flow laser. Its design is similar to the slow axial flow laser, except that a tangential blower

Fig. 3 Slow axial flow CO<sub>2</sub> laser

forces a large amount of laser gas axially down the resonator, as shown in Fig. 5. This increases the available power to 700 W/m (210 W/ft) of active laser resonator. This laser type is currently being built with power up to 3 kW and is becoming increasingly popular as a cutting laser because of its increased power, excellent beam quality, and pulsing capabilities.

Both the slow and fast axial flow lasers can operate in either the continuous wave (CW) or electronically pulsed modes. In CW operation, the laser operates at a continuous power level. This type of operation provides the highest cutting travel speeds. Because of the high speeds required to cut thinner material above 3175 mm/min (125 in./min), a loss of accuracy can occur on intricate parts because of motion

system limitations. Overheating will also occur on any thickness if the part is very complex. The solution to these problems is to pulse the laser electronically, thereby allowing intermittent high peak powers (approximately two to eight times the peak CW power) and overall lower average powers, as shown in Fig. 6. This results in controlled heat input and higher accuracies, but at reduced feed rates, compared to CW operation. Typical pulse rates for CO<sub>2</sub> laser cutting range from 100 to 1000 Hz.

## Nd:YAG Laser

The Nd:YAG is the second type of industrial laser. It is a solid-state laser in which the active

Fig. 4 Transverse or cross-flow CO<sub>2</sub> laser

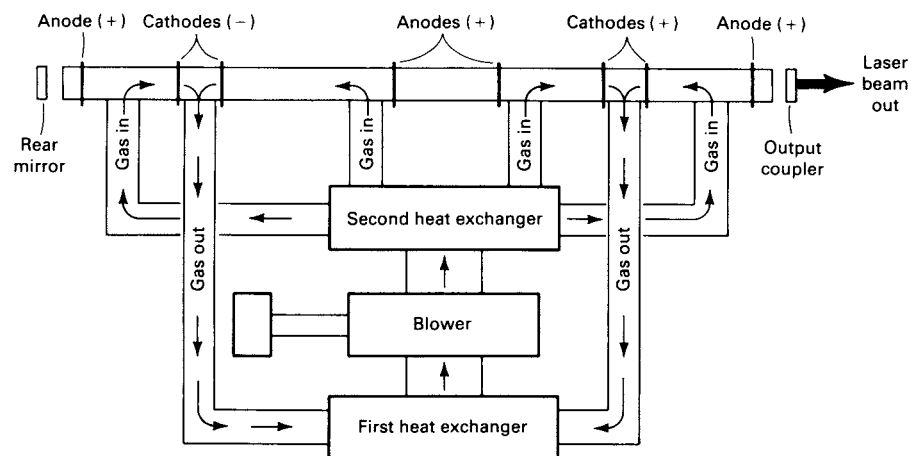

Fig. 5 Typical fast axial flow CO<sub>2</sub> laser

medium is neodymium, which is dissolved in a matrix of yttrium-aluminum-garnet. The resulting crystal is formed into a rod, which is excited by external flash lamps using xenon or krypton. As the lamps flash, the light is absorbed by the rod, exciting the medium to emit photons. This laser uses the same type of two-mirror resonator described earlier. The Nd:YAG laser is a pulse-only laser with a cutting speed limited to approximately 760 mm/min (30 in./min). This laser also emits invisible infrared light but with a wave length of 1.06  $\mu\text{m}$  (41.7  $\mu\text{in.}$ ), compared to 10.6  $\mu\text{m}$  (417  $\mu\text{in.}$ ) for a CO<sub>2</sub> laser. Because of this shorter wavelength, the Nd:YAG beam is more readily absorbed by metals and is therefore used to cut gold, silver, copper, platinum, and other metals that would be very reflective to a CO<sub>2</sub> laser. The Nd:YAG laser also does a superb job of drilling and trepanning small holes in metals and is typically used on aircraft jet engine parts made from high-temperature superalloys

and titanium. Figure 7 shows a typical Nd:YAG laser system design.

### Competing Cutting Methods

The advantages and disadvantages of several conventional metal-shaping processes that compete with the laser are shown in Table 4. While the laser does not displace any of these processes in terms of their special capabilities, laser cutting does fill a very important void. For example, the laser is the ideal method for producing short-run or prototype blanked parts of large, complex or small, intricate shapes (Fig. 8). The choice to laser cut these parts is based on

cost. The expense of temporary tooling or edge finishing far exceeds the cost of laser cutting.

A second, broader example is the cutting of industrial-quality circular saw blades. Several years ago, a major manufacturer of such blades purchased a two-axis laser system to blank out the entire saw blade. These saw blades are being produced in sizes ranging from 50 to 915 mm (2 to 36 in.) in diameter, with an average order quantity of 22 pieces. Because of the small order quantity and the highly customized tooth profiles, many setups and operations were required to punch the geometries. However, by using the laser, which cut the saw geometry in just one operation, the manufacturer was able to reduce the cost on many items up to 30% over

Fig. 6 Pulsed waveform

Fig. 7 Typical Nd:YAG laser design

Table 4 Advantages and disadvantages of laser cutting versus traditional metal-cutting methods

Cutting method	Advantages	Disadvantages
Laser	Good edge quality, good accuracy, small kerf, narrow HAZ, no distortion, little noise; cuts nonmetals, cuts small and complex shapes	High equipment cost, limited to under 13 mm (0.5 in.) thick, slower feed rates over 6.4 mm (0.25 in.); cuts single layer
Plasma arc	Lower equipment costs, faster feed rates over 6.4 mm (0.25 in.); cuts over 13 mm (0.5 in.) thick	Lower accuracy, decreased edge quality, larger kerf, wider HAZ, noisy, higher operating costs; only cuts metal
Laser	Good edge quality, good accuracy, lower scrap rate, no distortion, small kerf, no tooling or tool wear, increased part nesting; cuts complex shapes, cuts up to 13 mm (0.5 in.) thick, cuts tempered materials and nonmetals	Higher equipment costs, lower process rate, higher costs on larger part quantities
Nibbling (turret punch press)	Good process rate, lower equipment costs, economical on medium- to high-production runs	Lower edge quality, high tool wear, high tooling costs, low accuracy, distortion, scrap; only cuts 10 mm (0.38 in.) thick
Laser	Good edge quality, no tooling or dies, short setup times, rapid and low-cost design changes, noncontact cutting; cuts complex shapes and three-dimensional shapes, cuts tempered materials	Higher equipment costs, low rate on high volumes
Punch press	High volume rates; lower costs at high volumes; cuts over 13 mm (0.5 in.) thick	Greater tool fabrication time, higher tool costs and maintenance, more setup time, poorer tool design, part stresses, lower edge quality; only cuts annealed steel
Laser	High feed rate, economical on small and medium quantities; cuts nonmetals and nonconductive metals	Lower edge quality, higher equipment costs, thickness limitations
Wire electric discharge machining	Good edge quality, good accuracy, lower equipment costs; cuts over 13 mm (0.5 in.) thick, cuts very fine and complex shapes	Very slow on any thickness, fixturing
Laser	Narrow kerf, faster feed rates, good accuracy, good edge quality	Small HAZ, fumes; cuts limited materials
Abrasive waterjet	No HAZ; cuts up to 152 mm (6 in.) material thickness, no distortion, cuts all materials	Abrasive disposal, noisy, high-pressure plumbing, slow feed rates
Laser	Flexibility, faster feed rate, short setup time	Small HAZ, accuracy, high equipment costs
Numerically controlled milling	No HAZ, good accuracy, good edge quality, low equipment costs	Limited feed rate, high tool costs and maintenance

HAZ, heat-affected zone

conventional punching, milling, turning, and blanking methods.

Laser cutting does have limitations for many applications. In the case of the heat-affected zone and fusion layer present in some aerospace hardware, laser cutting can only be used to produce a semifinished part that requires further processing using a different method.

Laser-cutting advantages and disadvantages must be carefully considered for each particular application before deciding whether use of the laser is advantageous. Because applications are too far-ranging to generalize, in-depth information should be obtained from a laser manufacturer, systems house, laser job shop, or consultant.

## General Cutting Principles

The mechanism for cutting steel with a laser is basically the same as cutting steel with an oxygen-fuel process in which the fuel gas acts to heat the material so the oxygen can oxidize and react exothermically with the steel to produce the cutting action. The oxygen also helps to sweep the molten material out of the kerf. In laser cutting, the fuel gas is replaced with a laser beam focused to approximately 0.1 mm (0.004 in.), resulting in a power density of 1 MW/cm<sup>2</sup> (6.5 MW/in.<sup>2</sup>). It is this characteristic that allows a 3.94 mm (0.155 in.) thick alloy steel chain saw bar to be cut out at 2.54 m/min (100 in./min) with a 0.15 mm (0.006 in.) kerf width and without part distortion.

Laser cutting can also be accomplished on nonferrous and nonmetallic materials using assist gases. In the case of nonferrous metals (aluminum, copper, brass, and bronze), which have high thermal conductivities but do not react with assist gases and are reflective to the laser beam, cutting occurs when the laser beam heats the material well above its melting point, and an assist gas, such as air, argon, or helium, is used to sweep the molten material out of the cut. The inert gases are used only when the cut edge of the material must be free of any impurities that would reduce its serviceability in a very harsh environment.

In the case of nonmetallic materials with low thermal conductivities and high beam absorption, such as wood, cloth, and paper, vaporization of the material upon cutting is nearly 100%. Because material vapors have a tendency to rise, an assist gas, such as compressed air, is used at a low pressure to protect the focusing lens from the damaging vapors. Organic materials such as plastics and woods are also cut with lower gas pressures. Acrylic plastic will yield a fine polished edge if cut with an inert gas or compressed air at 70 kPa (10 psi) pressure. Table 5 summarizes the general purposes of assist gases.

## Process Variables

There are seven basic parameters in the laser-cutting process: beam quality (mode), power (CW or pulse), travel speed, assist gas, nozzles, focusing lens, and focal-point position. Slight

changes in any one of these parameters can yield significant changes in cut quality.

To fine-tune excellent cut quality, it is recommended that only one parameter at a time be varied, while the others remain constant. Laser processing maps (Ref 1) are also a method in determining appropriate parameters. Additional guidelines on laser cutting are available in Ref 3.

**Beam quality, or mode**, is a very important parameter. A laser should be used with a TEM<sub>00</sub> (TEM, transmission electron microscopy) or Gaussian mode, which is ideal for cutting (Fig. 9a). A Gaussian mode has most of its energy in its center. Figures 9(b) and (c) illustrate the power density versus the radial distance from the beam centerline for both TEM<sub>00</sub> and TEM<sub>01</sub>\* modes. The TEM<sub>00</sub> mode can be focused to a smaller spot size than can TEM<sub>01</sub>\* and has greater energy density of power per unit area, thereby increasing cutting efficiency. This TEM<sub>00</sub> mode decreases the heat input to the part, which allows faster cutting speeds and a smaller heat-affected zone (HAZ). Because the beam can be focused to a smaller spot size, kerf width is also reduced.

**Power** plays a significant role in respect to both feed rates and thicknesses. For example, Fig. 10 shows that increasing power increases speed and thickness for a given material, while holding all other parameters constant. Figure 10 also shows that the maximum material thickness to be cut also increases with increasing power. When pulse cutting is used, the average powers decrease, while the peak powers of each pulse increase from two to eight times the maximum CW power. This reduction of average power reduces the feed rate by approximately 60 to 80%.

**An optimal travel speed** exists that yields the best cut quality, while holding all other parameters constant. Because feed rate is very material dependent, experimentation is needed in order to obtain the best results. However, for most metals, the best cut is obtained at the

**Table 5 Assist gas usage**

Gas	Major function	Usage
Oxygen	Promotes chemical reaction	Cutting ferrous metals
Argon, helium, and nitrogen	Inhibit chemical reaction	Cutting thin metal for oxide-free edge; cutting chemically reactive metals and materials
Air and inert gases	Remove excess by-products	Lens protection, absorptive plume removal; cooling to clear hot gases away from thermally sensitive materials; cutting nonmetals

(b)

**Fig. 8** Typical laser-cut parts. (a) Ceramic. (b) Metal

maximum achievable speed, which also helps to minimize the HAZ. If the feed rate is too low, burning will occur, and a large HAZ with slag formation will be present. In nonmetals such as wood or cloth, excessive charring will be present on the cut face. If the feed rate is too fast, the

beam will climb out of the cut, and only partial cutting will occur.

**Use of oxygen as the assist gas** for cutting steel and stainless steel increases cutting speeds by 20 to 40% compared to use of air. Air is used mostly to cut nonmetals because it helps reduce oxidation and burning. When cutting stainless steel with an oxygen assist gas, slag or a fusion layer occurs, which is not tolerable in some applications. Although argon or helium assist gases eliminate oxidation, they reduce travel speeds by up to 50%.

**The gas nozzle design** and standoff distance, which is the distance between the workpiece and the nozzle, can significantly affect cut quality. A properly designed nozzle will produce a laminar, high-flow-rate assist gas through the cut. The laminar flow can be affected by the standoff distance. If the standoff distance is too great, the smoothly flowing gas tends to break up. This disrupts the flow through the kerf and decreases the edge quality. Typical nozzle diameters are 1 to 2 mm (0.040 to 0.080 in.) with 0.5 to 3 mm (0.020 to 0.12 in.) standoff distances.

**A focusing lens** is used to focus the beam on the workpiece. This increases the power density of the beam. The lens is used because the output beam of a laser is typically 11 to 21 mm ( $7/16$  to  $13/16$  in.) in diameter and does not possess enough energy per unit area to melt and vaporize materials. The lens can focus the beam to a spot size of 0.1 mm (0.004 in.) in diameter. The same principle is in operation as when using a magnifying glass to focus sunlight on a piece of paper, causing it to burn.

Lenses are classified by focal length, or the distance from the lens to the point at which the

spot size is smallest (Fig. 11). Typical lenses come with focal lengths that range from 38 to 254 mm (1.5 to 10 in.). Shorter focal-length lenses have higher energy densities because they have a smaller spot size, as shown in Fig. 12. These lenses, however, have a limited depth of field, or usable beam. Depth of field is the area of the focused beam that has enough energy density to process materials. This spot-size limitation can be offset by using a larger input beam on a longer focal-length lens, as shown in Fig. 13. Short lenses are typically used on reflective materials, such as aluminum, or on thin materials, for faster feed rates and an improved surface finish. Longer focal-length lenses are usually used on materials 6.4 mm (0.25 in.) or more thick because of their greater depth of field, which produces a squarer cut and sharper geometry definition at the bottom of the cut. Because of increased spot size, these lenses decrease feed rate and overall surface finish quality, while increasing the HAZ. Most lenses in use are between 64 and 127 mm (2.5 and 5.0 in.) in focal lengths.

**The focal point position** greatly affects the surface finish and dimensional accuracy of the part. Accuracy is affected because the beam is never parallel (Fig. 12); hence, as the focal point is moved to different positions, the kerf width can increase or decrease. This effect must be considered when cutting high-accuracy parts.

Surface finish is very dependent on the focal point. For the majority of metals, the focal point

**Fig. 11** Geometry of focused beam

is set slightly below the work surface. For other materials, such as stainless steels, the focus is set well below the surface of the material to yield the best cut. However, the focal position itself is very dependent on the type of material and other process parameters and therefore must be manipulated to find the optimal setting.

## Material Conditions

Several material conditions can affect the quality of the laser cut. First, surface cleanliness can have a detrimental effect on edge quality. All steel alloys should be either hot rolled, pickled, and oiled; or cold rolled. Mill scale, which can interfere with the beam, greatly reduces edge quality and dimensional accuracy. Rusted steel also decreases cut quality. No other special cleaning methods are required.

Second, flatness of the material to be cut affects the focal point of the beam. The focal point must be controlled to  $\pm 0.25$  mm

(0.010 in.) to achieve the best possible cut. Increasing surface roughness can deflect the assist gas, resulting in a nonlaminar assist gas flow, thereby decreasing edge quality. Most sheet steel is smooth enough to be laser cut.

Third, coatings on the material surface usually have no adverse effect on cutting. Thin layers of plastic on metal surfaces are cut without problem, although proper fume collection procedures must be used. Electrogalvanized steel can be laser cut, provided that the galvanized layer is thin. Again, it is recommended that fume collection be used. Steels with paint on one surface should be cut without oxygen because a paint-oxygen reaction produces a very poor cut.

Finally, the ambient temperature of materials must be taken into consideration. Because carbon steels react exothermically with oxygen at low temperatures of approximately  $40^{\circ}\text{C}$  ( $104^{\circ}\text{F}$ ), high ambient temperatures result in a cut with wide, rough, low dimensional accuracy. This effect also must be taken into account when cutting very intricate geometries in carbon steels. However, pulse cutting at reduced feed rates reduces the heat input and allows satisfactory cutting of very small and intricate shapes.

## System Equipment

The basic laser-cutting system consists of a laser, a motion system, a controller that is computer numerically controlled (CNC), and a beam delivery system. Optional equipment includes water chillers, dust/fume collectors, compressed air equipment, transformers and related electrical equipment, and a computer-aided design/computer-aided manufacturing (CAD/CAM) system. Typical costs for an installed system can range from approximately \$100,000 for a small, two-axis cutting system to over a million dollars for a large, five-axis cutting system.

Many styles and sizes of motion systems are available. The most popular is the *x-y* axis table system. The *x-y* motion is coordinated by a CNC

controller and is used to blank contours out of flat sheet stock. These systems range in size from 300 by 300 mm (12 by 12 in.) to 1.6 by 3.0 m (63 by 120 in.) for a large-bed sheet-cutting system. These two-axis motion systems are available in three styles, each of which manipulates the workpiece and/or beam differently in the course of contouring a part, as shown in Fig. 14.

The first system, shown in Fig. 14(a), has a moving workpiece and a stationary beam, which is the simplest and least costly system. Motion systems of this type usually provide the highest accuracies for laser cutting. For cutting areas

**Fig. 12** Beam diameters at equal distances from focus position for lenses of different focal length

**Fig. 13** Beam expansion for same spot size

(a)

(b)

(c)

**Fig. 14** Three types of two-axis motion systems. (a) Moving *x-y* table, stationary beam. (b) Moving *x*-axis table, moving *y*-axis beam. (c) Moving *x-y* beam, stationary table

larger than 1.2 by 1.2 m (48 by 48 in.), the mass of a two-axis table system becomes large and therefore reduces travel speeds and accuracies. For large-sheet cutting requirements, it is advantageous to move the workpiece in one axis, while moving the beam and cutting head assembly in the other axis, as shown in Fig. 14(b). This allows for significantly less mass movement on the motion system, while incorporating some floor space savings. For systems that are 1.2 by 2.4 m (48 by 96 in.) or larger, it is more common to move the beam and optics on a gantry-style motion system, as shown in Fig. 14(c). These systems do, however, require more attention to beam alignment. A moving optics system can also be used on smaller systems in which the parts are too heavy to move accurately, or on assembly lines.

Most laser-cutting systems usually employ some type of floating third, or z, axis to allow the focused beam to be introduced to the workpiece, because a workpiece is not usually perfectly flat. These floating cutting heads sense height changes through contact and noncontact methods. Figure 15 shows a contact method using roller balls.

Other types of motion systems have three, five, seven, and nine axes of programmable motion. The three-axis systems have either a programmable z or a rotary axis. The z-axis allows cutting on parts with different heights, whereas a rotary axis allows contour cutting of tubing. The five-axis gantry-style motion systems incorporate x, y, and z axes, with a wrist on the z-axis. A wrist is a set of orthogonal rotating mirrors providing increased beam manipulation. This system allows contour cutting on formed parts and is necessary because the beam must be normal to the surface being cut. Typical applications are

the trimming of stamped parts such as automotive and motorcycle fenders. In specialized cases, a nine-axis robot can manipulate either the beam or the workpiece. Some applications include cutting holes for sunroofs in auto assembly lines or other types of ventilation.

A CNC controller is used to coordinate the motion and the laser operation. The controller reads standard numerically controlled (NC) programs that describe the contour to be cut. The NC programs are prepared with a CAD/CAM system. Then, either the NC file is punched on paper tape and read into the controller by a tape reader or a number of other methods, including floppy disks, erasable programmable read-only memories, and a direct numerical control between the controller and the off-line computer.

A dust/fume collecting system should be installed: Laser cutting of metallics produces dust, which should be removed, while non-metallics can produce smoke and fumes, which can be irritating and/or hazardous and likewise should be removed from the work area. Optional equipment includes a water chiller to cool the laser and external optics, transformers for proper electrical supply, and compressed dry air for the beam delivery and assist gas.

## Laser-Cutting Applications

Virtually any metal can be laser cut. The conditions for cutting some metals, however, are difficult to obtain. Following is a general description of how well each metal group can be cut. Additional information on laser cutting of engineering materials is in Ref 1.

**All carbon and alloy steels** can be laser cut to over 13 mm (0.50 in.) thick with an oxygen assist gas. As Fig. 10 shows, the feed rates are dependent on available power at the workpiece. A general rule of thumb is that for a given thickness, the feed rate increases approximately 50% when power is doubled. The resulting kerfs can be as small as 0.1 mm (0.004 in.) thick with a 65 mm (2½ in.) focal-length lens. The resulting HAZ is small (approximately 0.1 to 0.3 mm, or 0.004 to 0.012 in.), depending on thickness and speed. The edges are clean, smooth, and square.

Higher-carbon steel exhibits an improved edge quality, although the HAZ is slightly larger and harder. Impurities of phosphorus and sulfur can cause some edge burning: Lower-quality steels exhibit this edge burning, whereas alloy steels generally do not. In fact, the alloy steels, such as chrome-nickel-molybdenum (for example, 4340) and chrome-molybdenum (for example, 4130), are perfect candidates for extremely high-quality edges that are very smooth and clean. These steels do, however, require approximately 50% more time to pulse a starting hole than is the case with a similar thickness of plain carbon steel. Another consideration is that the HAZ is slightly larger and harder (approximately 45 to 60 HRC), depending on the alloy and carbon content. This means that further

processing can be difficult on the laser-cut edges unless they are annealed.

Laser-cut tool steels have almost the same results. The exceptions are the alloys that have very dense alloying elements, such as tungsten. These alloys retain a large amount of heat when molten, which helps to limit thickness and produce very rough cuts having heavy slag deposits. The air- and oil-hardened alloys exhibit very good edge quality and can be cut up to 10.2 mm (0.400 in.) thick at approximately 0.8 m/min (32 in./min) at 1300 W. Alloys such as D-2 and M-2 can only be cut up to approximately 4 mm (0.160 in.) thick with the same power.

**Stainless steel** alloys are also readily cut using a laser. The feed rates are reduced, however, because these alloys do not react as effectively with oxygen as carbon steel alloys do. An inert assist gas may be used to obtain a weld-ready edge, free of all oxides, at the expense of approximately one-half the oxygen-assisted speed. Stainless steels maintain their corrosion resistance because the HAZ is small.

In general, the ferritic (400-series) stainless steels produce smoother cuts with less slag than austenitic (300-series) stainless steels do. These stainless alloys do not contain nickel and can be cut to approximately 6.5 mm (0.260 in.) thick.

The added presence of nickel does affect the energy coupling and heat transfer in the alloy. This means that these alloys are not effectively laser cut above 5 mm (0.197 in.) thick. The viscosity of the molten nickel is very high and has a tendency to migrate and adhere to the bottom of the cut. This increases the heat in the metal and produces a large HAZ, as well as a rough cut starting approximately one-third to one-half the way through the material. This effect can be reduced by using high-pressure assist gas jets or rapid-cooling methods (such as water) in the cut.

**Nonferrous Alloys.** Aluminum alloys can readily be laser cut but only to approximately 4 mm (0.160 in.) thick. The thickness is limited because aluminum has high reflectivity at infrared wavelengths and high thermal conductivity. To overcome these effects, the laser must have a TEM<sub>00</sub> mode, which allows for tighter focusing and higher power outputs, that is, 500 W or more. To further improve the cutting, short focal-length lenses and high assist gas pressures help reduce and/or eliminate slag that forms when molten material is blown to the back side of the cut and solidifies; the slag is very easily removed. Feed rates are generally 25% slower than when laser cutting stainless steels.

Copper, brass, and bronze are even more reflective and heat conductive than is aluminum. Because brass and bronze are alloys of copper, they can be laser cut, but with limited thickness and speed. The cuts can be rough, and a slag is present on the bottom of the cut. Copper has been cut under ideal conditions in thicknesses up to 6.35 mm (0.25 in.) with 1200 W. The speeds are extremely slow, so practical upper cutting is limited to approximately 2.6 mm (0.100 in.).

Fig. 15 Cutting head design

Other high-tech alloys can also be laser cut. Titanium cuts very well up to approximately 7 mm (0.275 in.) thick. An inert assist gas is usually employed to prevent an oxide layer from forming. Oxygen can be used, but because titanium reacts very strongly with it, high feed rates are needed to prevent burning the material.

**Nonmetal Cutting.** Most nonmetals rely on the same technique for laser cutting. The cutting action is dependent on the ability of the laser beam to be absorbed by and to vaporize the material being cut. Because the cut does not rely on an oxidation reaction, as in steel cutting, the laser vaporizes the material with the aid of an assist gas (either inert gas or compressed air) to help purge the cut of the vaporized material. The CO<sub>2</sub> laser is typically preferred for nonmetal cutting because of its good absorption by many materials and its high cutting speeds.

Acrylic is easily cut with the CO<sub>2</sub> laser. Thicknesses up to 50 mm (2 in.) have been cut for aircraft windshields, but most work is done at thicknesses of approximately 6.4 mm (0.25 in.), while a 150 W unit provides speeds of 1.25 m/min (50 in./min). The cut edge is usually frosted at these speeds. A fine polished edge is attainable in acrylic at approximately half speed with very low assist gas pressure.

Quartz and nontempered glass are commonly cut for a variety of applications. The edge quality of glass is rough compared to laser cuts in most other materials, at speeds up to 2.5 m/min (100 in./min) for a 3 mm (0.10 in.) thickness

using a 600 W CO<sub>2</sub> laser, and approximately 5 m/min (200 in./min) for a 1200 W unit.

Quartz, on the other hand, cuts with a fine, clean edge with speeds of 5 m/min (200 in./min) for 1 mm (0.040 in.) thick material and 1 m/min (40 in./min) for 3 mm (0.10 in.) at the 600 W level.

Ceramic of 96% Al<sub>2</sub>O<sub>3</sub> (alumina) is used for electronic substrates and is very brittle; the noncontact cutting characteristic of the laser therefore makes it the preferred method. The laser is used in the pulse mode to minimize heat input to the part. A high-quality edge is produced at 0.5 m/min (20 in./min) for alumina substrates up to 1 mm (0.04 in.) and 0.25 m/min (10 in./min) in the 1 to 2 mm (0.04 to 0.08 in.) range with a 500 W CO<sub>2</sub> laser in the pulsed mode.

Aramid fibers have tensile strengths that exceed those of steel. The fiber is woven into sheets for use as bullet-proof vests and is bonded in layers with epoxy for structural aircraft parts. Its high strength makes it very difficult to cut with conventional cutting methods. The CO<sub>2</sub> laser cuts with high travel speeds and can bond the cut edges of aramid and most other woven fabrics to prevent fraying. Aramid, bonded in layers with epoxy, can be cut in thicknesses up to 10 mm (0.40 in.). Because of the nature of the epoxy, the cut edge of the aramid-epoxy composite is darkened upon laser cutting. This is more pronounced in thicker samples with heavy epoxy layers. At the 600 W level, typical speeds are 12.75 m/min (500 in./min) for 1.25 mm

(0.05 in.) thick material and approximately 7.75 m/min (300 in./min) for 3 mm (0.10 in.) aramid-epoxy composites.

Intricate shapes can be cut from wood with thicknesses well over 25 mm (1.0 in.). A solid wood product cuts very nicely and leaves a smooth but darkened edge. A popular application is cutting patterns in 15 to 19 mm (0.60 to 0.75 in.) beech plywood for steel rule die boards. Speed and focus changes create different width slots for different width blades (up to approximately 2 mm, or 0.08 in.). Therefore, speeds range from 0.5 to 1.8 m/min (20 to 70 in./min) for a 600 W CO<sub>2</sub> laser.

# Abrasive Waterjet Cutting

ABRASIVE WATERJET CUTTING operates by the impingement of a high-velocity abrasive-laden fluid jet against the workpiece, yet it produces no heat (and therefore no heat-affected zone) to degrade metals or other materials. The finished edge obtained by the process often eliminates the need for postmachining to improve surface finish.

A coherent fluid jet is formed by forcing high-pressure abrasive-laden water through a tiny sapphire orifice. The accelerated jet exiting the nozzle travels at more than twice the speed of sound and cuts as it passes through the workpiece. Cuts can be initiated at any point on the workpiece and can be made in any direction of contour—linear or tangential. The narrow kerf produced by the stream results in neither delamination nor thermal or nonthermal stresses along the cutting path.

In addition to applications in the machining of superalloys; armor plate; titanium; and high-nickel, -chromium, and -molybdenum alloys, abrasive waterjet machining can also be used to cut concrete, rock, glass, ceramics, composites, and plastics. The ability of the abrasive waterjet to cut most metals without any thermal or mechanical distortion places this innovative process on the leading edge of material cutting technology.

## Process Development

In 1968, Dr. Norman Franz filed his first patents on the use of high-pressure water streams to cut materials. The first commercial application of this process, in 1971, involved the cutting of 9.5 mm ( $\frac{3}{8}$  in.) thick pressed board for manufacturing furniture forms. Since then, numerous waterjet units have been installed by various manufacturers worldwide. Waterjet cutting technology, which involves pumping a 0.08 to 0.46 mm (0.003 to 0.018 in.) diameter water stream at 207 to 414 MPa (30 to 60 ksi), was initially developed to cut or slit nonwoven materials, fiberglass building products, corrugated box materials, and plastics.

It was later found that hard or extremely dense materials such as metals and aerospace composites could be cut when particles of dry abrasives such as garnet and silica were added to the waterjet. This modification produced the

abrasive waterjet and is responsible for the ability to cut advanced materials much more efficiently than with standard mechanical or thermal cutting methods. With abrasives added to the waterjet, the liquid stream itself is merely the medium that propels the abrasive instead of being the primary cutting force.

Abrasive waterjet cutting is used to cut metals and composite materials, such as boron/aluminum honeycomb, aluminum/boron carbide, and graphite composites, into intricate shapes and curves with virtually no heat input into the workpiece. It has been in use in industrial applications since 1983.

## Advantages and Limitations

**Advantages.** The advantages of abrasive waterjet machining are summarized as follows:

- Ability to cut through most sections of dense or hard materials, such as metals and glass, leaving a clean, finished edge—3.2 to 6.3  $\mu\text{m}$  (125 to 250  $\mu\text{in.}$ ) roughness with 60-, 80-, or 100-grit abrasive at 0.22 to 1.1 kg/min (0.5 to 2.5 lb/min)—without the need for secondary machining
- Ability to produce contours, shape-cutting, bevels of any angle, and three-dimensional profiling, because the process is omnidirectional
- Easy integration into computer-controlled systems, optical tracers, and full-scale six-axis robots. The cutting head weighs as little as 4.5 kg (10 lb) for easy mounting on robotic arms; precision robotics can accommodate cutting heads weighing 23 to 32 kg (50 to 70 lb)
- Wide availability and low cost of garnet and silica, the most common abrasive materials used
- Low water consumption (0.473 L/min, or 0.125 gal/min), which translates to 28 L/h (7.5 gal/h) despite the high pressures used
- No heat-affected zone
- Simple workpiece tooling, because the jet delivers approximately 2 to 9 N (0.5 to 2 lbf) of vertical force
- Finished part tolerance of 0.075 to 0.25 mm (0.003 to 0.010 in.) with conventional abrasive waterjet cutting of materials under 50 mm (2 in.) thick

**Limitations.** This device cannot replace tools that mill, turn, or drill blind holes or perform other operations that involve cutting or drilling to a partial depth. Glass and composite materials should be pierced at low pressures (70 to 83 MPa, or 10 to 12 ksi) to minimize chipping and delamination. Tempered glass is an example of one material that should not be machined with an abrasive waterjet. Other limitations are:

- Cutting through air gaps, such as cutting a pipe, causes the jet to flare out as it cuts through the first layer and produces a distorted, wider kerf cut through the second layer.
- The abrasive waterjet is typically used to cut all the way through a material, and only with special equipment and for special applications can it mill a blind hole or drill to partial depth.
- Glass and composite materials should be pierced at low pressures (70 to 85 MPa, or 10 to 12 ksi) to minimize chipping and delamination. Tempered glass is an example of one material that should not be machined with an abrasive waterjet, or any other process for that matter, because tempered glass requires the stresses to be sealed at the glass edge—relieving that seal will result in the glass breaking.
- The surface produced is a satin-smooth, sand-blasted finish. Finishes better than 1.5  $\mu\text{m}$  (60  $\mu\text{in.}$ ) RA (roughness average) are difficult or not possible.
- The smallest internal radius that can be produced on a material is 0.25 mm (0.010 in.).

## Cutting Principle

The abrasive waterjet cuts material by the action of abrasive solids (entrained by the waterjet) on the workpiece. Depending on the properties of the material, cutting occurs by erosion, shearing, failure under rapidly changing localized stress fields, or micromachining effects. A small abrasive jet nozzle is used (Fig. 1). Water is pressurized to 414 MPa (60 ksi) and expelled through a sapphire nozzle to form a coherent high-velocity (914 m/s, or 3000 ft/s) jet. A stream of abrasive particles is introduced into the nozzle to form a concentrated abrasive jet slurry (0.5 to 2.5 kg/L, or 4 to 20 lb/gal). The momentum of the waterjet as it travels toward

the nozzle is transferred to the solid particles, and thus their velocities are rapidly increased.

This momentum transfer between the waterjet and the abrasive is a complex phenomenon. There is a limited dynamic stability of the high-pressure waterjet, and it breaks into droplets that accelerate the solid particles. In addition, the solid particles impose drag forces on the waterjet.

The result of this momentum transfer between the water and the abrasive particles is a focused high-velocity stream of abrasive. The cutting rate is controlled by changing the feed rate, the standoff distance, the waterjet pressure, or the abrasives.

## Abrasive System Components

The primary components of an abrasive waterjet cutting system are the high-pressure water

pump, the nozzle assembly, and the abrasive catcher assembly. These components are connected by a network of hoses and swivels and are controlled by a system of control valves and sensors (Fig. 2).

**High-Pressure Water Pump.** Two types of high-pressure water pumps are used: a triplex pump and an intensifier pump.

A *triplex pump* operates in the same manner as a low-pressure "pressure washer" used to pressure wash. It is a pump that operates from three plungers connected to a crank. These pumps are simpler than intensifier pumps and deliver 140 to 380 MPa (20 to 55 kpsi) water pressure and come in a variety of horsepower and gallon per minute output capacities. A popular size is a 22 kW (30 hp) triplex pump delivering 3 L/min (0.82 gal/min) or 380 MPa (55 kpsi) of water. Although the triplex pump is gaining use, the intensifier pump is the original method of pressurizing water for waterjet cutting.

**Intensifier pumps** create water pressures of 210 to 415 MPa (30 to 60 kpsi) and flow rates to 13 L/min (3.5 gal/min). A motor drives a hydraulic radial piston with an intensification ratio of 20 to 1; that is, the water pressure is twenty times the oil pressure.

The pressure intensifier principle is best illustrated by the force equilibrium of the double-acting piston (Fig. 3). Hydraulic oil pressure acting on the piston results in a force on the plunger pressurizing the water in the small chamber. Force equilibrium is achieved when the water pressure equals the hydraulic oil pressure multiplied by the effective area of the piston divided by the area of the plunger (assuming no friction losses). The ratio of the effective piston area to the plunger area is termed the pressure intensification ratio. Because the intensification ratio is constant by virtue of the fixed piston-to-plunger-diameter ratio, water pressure can be regulated by controlling the hydraulic oil pressure.

To dampen pressure oscillations in the high-pressure output, the high-pressure water is routed to a shock attenuator. Sensors are installed throughout the intensifier pump to monitor flow

Fig. 1 Cross-sectional view of abrasive nozzle assembly showing path of water and abrasives

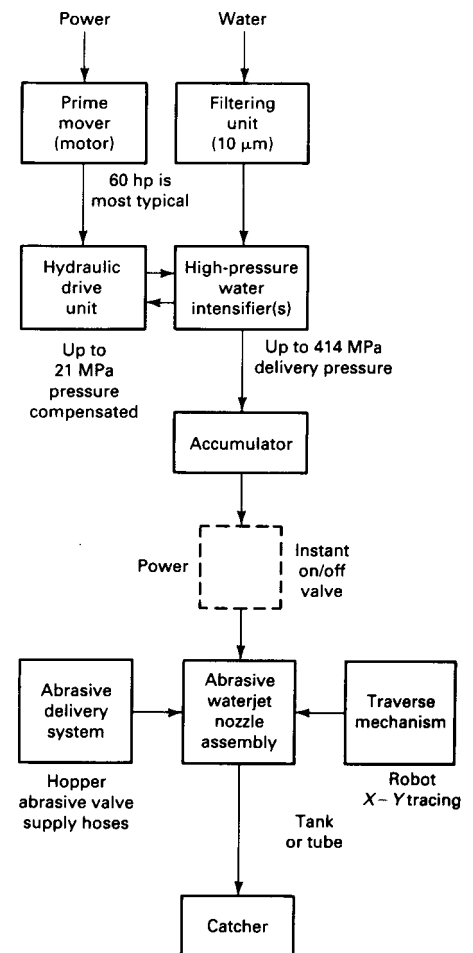

Fig. 2 Block diagram of abrasive waterjet system components

rates, temperatures, fluid levels, and operating conditions. Before the water enters the intensifier pumping system, it is filtered in three stages from 10 to 1 to 0.05  $\mu\text{m}$  (400 to 40 to 2  $\mu\text{in.}$ ) to remove small particles of matter and minerals that could damage seals and valves of the pump. It is necessary to prevent cavitation of the water as it enters the intensifier pump systems. The inlet water pressure is increased to a minimum of 410 kPa (60 psi).

The microprocessor-based controller, through operator-actuated keypad commands, determines the oil pressure delivered to the intensifier by the electric motor driven hydraulic pump. Incoming filtered water is pressurized through the principle of water intensification and routed to the waterjet cutting equipment. Figure 4 illustrates the principal parts of the intensifier pump.

**Particle Stream Erosion Nozzle.** The high-pressure water is directed through a tiny sapphire, ruby, or diamond orifice to form a coherent fluid jet. Then, after this supersonic pure waterjet has been formed, a carefully metered amount of

**Fig. 3** Cross-sectional view of the pressurization of water to 414 MPa (60 ksi) using the fluid pressure intensifier principle

dry abrasive is pulled into the cutting stream via a venturi effect and accelerated by the waterjet. The tiny orifice is approximately 0.13 to 0.5 mm (0.005 to 0.020 in.) in diameter. After the dry abrasive particles are fed into the mixing chamber (by the venturi effect), the abrasive stream is then directed through a 0.5 to 2.3 mm (0.020 to 0.090 in.) diameter tungsten carbide nozzle. At this point, cutting of material takes place directly under the nozzle as both water and abrasives exit the nozzle at velocities of approximately 640 m/s (2100 ft/s) in a coherent, focused stream ranging in diameter from 1.0 to 1.5 mm (0.040 to 0.060 in.).

Operating life of a synthetic sapphire orifice, which has a 5 min replacement time, is 250 to 500 h. The operating life of the tungsten carbide abrasive nozzle is limited to 0.50 to 6 h because of the erosive effects of the accelerated water/abrasive stream.

**The abrasive waterjet catcher system** collects the spent fluid after it passes through the material being cut. The design of the catcher system is based on whether the cutting system uses a stationary nozzle or a moving nozzle. For a stationary nozzle, the workpiece is fed to the cutting operation, and a tank is used to collect the spent fluid (Fig. 5). A moving nozzle can be used with the same type of setup if the cutting area is contained within the tank area. The tank should be lined with ceramic pieces to suppress the cutting or piercing of the tank lining by the abrasive waterjet. Multiple pieces of concrete block, brick, thick slate, and white iron have been used to alleviate this problem. The pieces work well with a moving nozzle but must be moved or replaced at varied intervals. Abrasives

settle to the bottom, and the tank requires periodic cleaning. The accumulated water is drawn off through a valve placed low in the tankwall.

A system incorporating a funnel-shaped catcher containing metallic shot to disperse the energy of the liquid has been designed for use with a movable nozzle. This device has a relatively long life expectancy as a catcher.

## Abrasives

**Surface finish** is an important part of the performance, wear, and appearance of a product. Parts may perform better or may have a higher fatigue strength or a better appearance with a higher degree of surface finish.

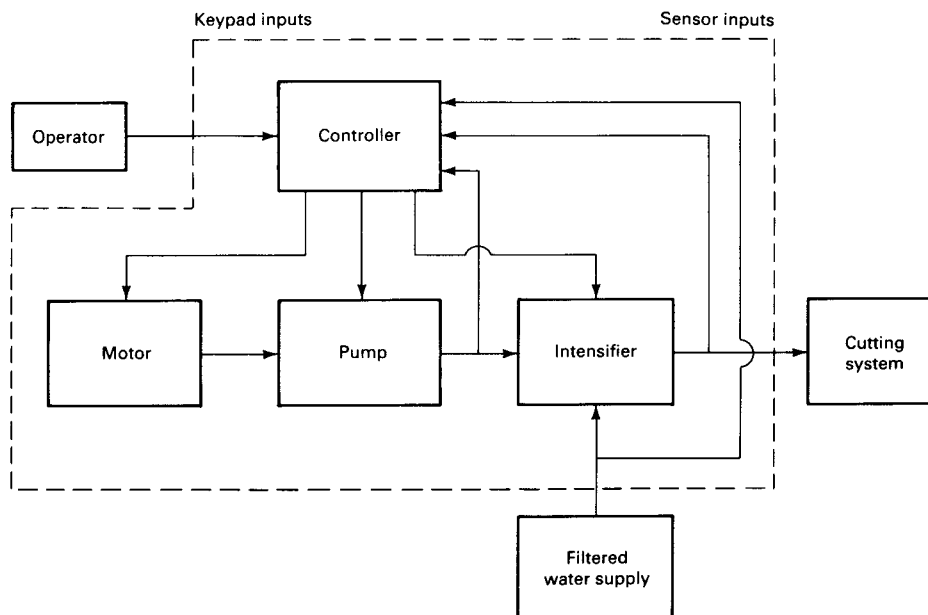

Two distinct surface textures are produced when cutting with an abrasive waterjet. The top half of the thickness may have a surface roughness of 3.3 to 10  $\mu\text{m}$  (130 to 400  $\mu\text{in.}$ ). The bottom half of the cut may have striations formed by the exit of the garnet from the workpiece (Fig. 6).

**Garnet versus Silica.** Tables 1 and 2 list surface finish ranges for garnet and silica abrasives. The following conclusions can be drawn from these data:

- Traverse cutting speed is the most important variable affecting surface finish.
- Flow rate is the second most significant variable affecting surface finish.
- Pressure is an important variable affecting surface finish but is dependent on the specific garnet size.

**Fig. 5** Stationary waterjet nozzle cutting through a movable workpiece (René 100 alloy gating contacts). Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island

**Fig. 4** Block diagram of intensifier pump assembly and its relationship to the microprocessor-based controller and cutting system

- Garnet will cut faster than a comparably sized silica abrasive.
- A 60-grit garnet will cut 23.5% faster than a 60- to 80-grit silica abrasive.
- Silica sands produce a higher-quality surface finish than garnet.
- The highest-quality surface finish occurs with the slowest comparable cutting speed and at the highest flow rate for both garnet and silica.

Thus, garnet is an effective abrasive. Silica sand may be adequate for cleaning operations involving the cutting of thin metals or

composites. Abrasives such as aluminum oxide or silicon carbide should be used for tough materials such as ceramics. However, these harder abrasives generally decrease the life of the nozzle.

Angular grain shapes will shear the workpiece much more efficiently than round grain abrasives. The abrasive particles should be of uniform size.

**Reclaiming** of abrasives is not feasible, because much time and effort would be required in drying and then regarding the particle sizes. The amount of abrasive that would be reusable does not warrant the expense. New graded garnet

and silicon sands are readily available and inexpensive.

**Cleanup and disposal** of the abrasive fluid can be a problem. Because the spent abrasive slurry has the consistency of mud, it is advisable to wait until the slurry is dry before attempting cleanup and disposal. Garnet is environmentally safe to dispose of. However, the particles mixed in with it from the material being cut may be classified as hazardous waste, and its disposal may be subject to both state and federal environmental regulations.

## Abrasive Waterjet Speeds

As the water pressure, flow rate, and therefore the horsepower increase, so does the cutting speed. As cut speed increases, the cost per inch decreases and abrasive flow rate increases. Eventually, a point is reached where more abrasive will overburden the process and reduce the cut speed and increase cost per inch. Therefore, a peak performance point exists for the abrasive flow rate. Today's (2005) systems are designed to fix the system at this peak point for all but the most custom applications. Maximum separation cut speeds with a standard abrasive waterjet system delivering 3 L/min (0.8 gal/min) of 415 MPa (60 kpsi) water and 0.5 kg/min (1.2 lb/min) of 80-mesh abrasive are listed in Table 3 for various materials. To obtain a high-quality finish, multiply the maximum speeds in Table 3 by 0.3 to 0.4. Various grades of a metal

**Fig. 6** Striations formed by the exit of garnet abrasives at the bottom of a workpiece. Material is 22 mm (7/8 in.) thick 4340 steel cut at 38 mm/min (1 1/2 in./min). Top surface has a 3.6  $\mu\text{m}$  (140  $\mu\text{in.}$ ) surface finish; bottom surface has a 4.7  $\mu\text{m}$  (185  $\mu\text{in.}$ ) surface finish. **Fig. 7** Water pressures and garnet abrasive flow rates versus piercing times for 9.5 mm (3/8 in.) thick 6061-T6 aluminum. Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island

(e.g., type 304 stainless steel, mild steel, etc.) have little effect on cut speed.

In addition to empirical testing, the abrasive waterjet process has been successfully mathematically modeled based on the abrasive waterjet process parameters, material type, material thickness, and desired edge quality. Intelligent control systems and software products allow users to enter these parameters and obtain the resulting cut speed. Operators simply type in the current jet setup, material type, thickness, and desired surface quality, and the machine does the rest. Some sample calculations follow.

**Calculation of Abrasive Waterjet Speeds.** The following parameters are assumed:

- Sand flow rate of 0.68 kg/min (1.5 lb/min)
- Water flow rate of 4.5 L/min (1.2 gal/min)
- Jewel size of 0.46 mm (0.018 in.) diameter

Using the continuity of momentum equation and assuming that the water is not compressed at all, the theoretical (ideal) velocity of the water exiting the jewel orifice is 461 m/s (1513 ft/s), and the theoretical velocity of the garnet and water at the nozzle is 402 m/s (1319 ft/s).

If, instead of 4.5 L/min (1.2 gal/min), it is assumed that the water flow rate is 3.84 L/min (1 gal/min)\* and that the water is compressed by 8%, the actual flow rate is 3.5 L/min (0.92 gal/min). Therefore, the actual velocity of the water exiting the jewel orifice is 354 m/s (1160 ft/s), and the actual velocity of the garnet and water at the nozzle is 297 m/s (973 ft/s). The speed of sound under normal atmospheric conditions is approximately 335 m/s (1100 ft/s).

The following examples illustrate the effect of different water pressures and garnet flow rates on a single thickness of two different metals as well as the effects of these variables on different thickness of one metal.

**Example 1: Analysis of Varying Water Pressures and Garnet Flow Rates on 9.5 mm (3/8 in.) Thick 6061-T6 Aluminum and 6.4 mm (1/4 in.) Thick Type 304 Stainless Steel.** All piercings were made with a 3.2 mm (1/8 in.) nozzle standoff having a 1.6 mm (0.062 in.) nozzle diameter. The garnet flow rates were 0.23, 0.45, 0.68, 0.79, and 0.91 kg/min (0.5, 1.0, 1.5, 1.75, and 2.0 lb/min). The water pressures were 55, 70, 105, 140, 170, and 205 MPa (8, 10, 15, 20, 25, and 30 ksi). The water pressure was held constant at 205 MPa (30 ksi) for the cutting, and the garnet flow rates were varied at 0.45, 0.68, and 0.91 kg/min (1.0, 1.5, and 2.0 lb/min).

Figures 7 and 8 show that much more time is required for piercing stainless steel than for aluminum at low water pressure. This reflects the hardness of the stainless steel. Although the two metals are not the same thickness, similarities between Fig. 7 and 8 are evident.

\*This flow rate is calculated by counting the number of times the intensifier pump cycled in 1 min. With this particular configuration, it cycled 50 times. The result obtained is (50 cycles/min) (0.076 L/cycle) = 3.8 L/min, or in English units: (50 cycles/min) (0.02 gal/cycle) = 1.0 gal/min.

The garnet flow rate affects the piercing time. High garnet flow rate versus low garnet flow rate, with pressure being constant, requires a longer time for piercing.

Figure 9 shows that piercing time acts as an exponential function relating to thickness. The same trend can be seen with garnet flow rates of 0.45, 0.68, and 0.79 kg/min (1.0, 1.5, and 1.75 lb/min).

Pieces that were not cut completely through had small ridges in the half kerf of the cut. The number of ridges in the cut corresponded to an equal number of cycles of the intensifier pump.

At cutting speeds greater than 100 mm/min (4 in./min), a noticeable taper was evident in the kerf width. At cutting speeds less than 100 mm/min (4 in./min), no significant taper was evident. Varying the garnet flow rates had no significant effect on the width of the kerf.

Similar characteristics were found in the cutting of stainless steel and aluminum. There is a rounding effect, and the kerf is larger for cuts at the same speed but increasing garnet flow. As aluminum thickness increased to 38 mm (1½ in.), higher water pressure was needed with an increase in the garnet flow rate.

**Example 2: Analysis of Varying Water Pressures and Garnet Flow Rates on Several Thicknesses of 6061-T6 Aluminum Bar Stock.** A piece of aluminum 6061-T6 bar stock 64 mm (2½ in.) wide by 38 mm (1½ in.) thick and 610 mm (2 ft) long was machined down to provide step thicknesses of 6.4, 9.5, 13, 19, 25, 32, and 38 mm (¼, ⅜, ½, ¾, 1, 1¼, and 1½ in.), as shown in Fig. 10(a).

Each section was pierced at several garnet flow rates with varying water pressures. The water pressures were 83, 103, 138, 172, and 207 MPa (12, 15, 20, 25, and 30 ksi). The garnet flow rates were 0.23, 0.45, 0.68, 0.79, and 0.91 kg/min (0.5, 1.0, 1.5, 1.75, and 2.0 lb/min).

The times were recorded using a digital timer connected to the robot controller. A new 1.6 mm (0.062 in.) nozzle was used with a 3.2 mm (⅛ in.) standoff.

**Table 3 Abrasive waterjet cutting speeds of various materials**

Material	Thickness		Maximum cutting speed(a)	
	mm	in.	cm/min	in./min
Aluminum	6	0.25	178	70
	13	0.5	100	40
	25	1.0	45	18
Marble	6	0.25	380	150
	13	0.5	178	70
	25	1.0	76	30
Steel (mild or stainless)	6	0.25	63	25
	13	0.5	28	11
	25	1.0	11	4.5
Titanium	6	0.25	76	30
	13	0.5	35	14
	25	1.0	15	6

(a) Cutting speeds with a standard waterjet system delivering 3 L/min (0.8 gal/min) of 415 MPa (60 kpsi) pressurized water with 0.5 kg/min (1.2 lb/min) of 80-mesh abrasive. Courtesy of Flow International Corp.

An evaluation of the piercings illustrated that the entrance and exit hole sizes reflected the water pressure, sand flow, and section thickness (Fig. 10b). With the 0.23 kg/min (0.5 lb/min) garnet flow rate, there was a slight overall decrease in hole size as the section thicknesses were reduced.

## Factors Affecting Cut Quality

**Bending of the kerf** can be readily seen in the Plexiglas (Rohm and Haas Company) piece shown in Fig. 11. This bending motion occurs because the abrasive stream loses energy as it cuts and travels further down into the target piece and becomes progressively less efficient. Meanwhile, the nozzle is still moving and cutting the material at the top, and this forces the kerf to bend away from the direction of the motion of the nozzle. Slowing down traverse speed or increasing cutting power will mitigate this phenomenon.

At high traverse speeds—especially in thick materials—this bending of the kerf will be most noticeable at the very end of the material. This is the case with the 50 mm (2 in.) thick semi-hardened steel section shown in Fig. 12. Because the bend is a smooth one, the cutting action at the bottom depends on the continual cutting at the top. When the end of the material is reached, there is a sudden interruption in this bend, and the jet stream is no longer deflected onto the uncut bottom section. This leaves an uncut crescent-shaped piece at the very bottom of the end of the cut that must be cut again or broken apart by hand. This problem can be alleviated if the computer program of the robot includes provisions for either slowing the traverse rate at the very end of the cut so that the stream is barely bent and/or changing the approach angle of the nozzle at the very end of the cut.

**Incomplete Initial Cuts.** The effects of an incomplete first cut can be seen in the Plexiglas shown in Fig. 11 and in the cut tantalum-silicon

**Fig. 8** Water pressure and garnet abrasive flow rates versus piercing times for 6.4 mm (¼ in.) thick type 304 stainless steel. Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island

piece shown in Fig. 13. A very poor surface finish can be expected at the bottom of the cut if the abrasive waterjet stream does not cut completely through the material on the first attempt. At the

bottom of the cut, where the cutting power of the garnet is expended, there are rough ridges, and the kerf width is greatly expanded because of the bouncing around of the excess garnet. This wider

kerf and expanded area are especially noticeable on the cut surfaces of the tantalum-silicon piece (Fig. 13).

**Special Precautions for Thicknesses Over 6.4 mm (1/4 in.).** Tantalum-silicon and Plexiglas samples up to 102 mm (4 in.) thick have been successfully cut with an abrasive waterjet. In cutting any material over approximately 6.4 mm (1/4 in.) thick, special precautions should be taken if a corner cut is to be made in the piece or if the material is to be pierced and then line cut.

When the Plexiglas piece shown in Fig. 11 was pierced, the hole itself was very smooth. However, when a traverse motion was initiated after piercing, the bending of the stream caused a section to the left of the hole to be cut away. This was not the desired effect. The same problem can occur when attempting a turn in the middle of the piece. The stream cannot simply bend around the turn. The nozzle must be stopped for a sufficient amount of time to allow the bend to

**Fig. 9** Garnet abrasive flow rates and section thickness versus piercing times for 6061-T6 aluminum at a water pressure of 207 MPa (30 ksi). Source: Department of Industrial and Manufacturing Engineering, University of Rhode Island

(a)

(b)

**Fig. 10** Two views of various thicknesses of 6061-T6 aluminum used in piercing studies with varying pressure and garnet flow rates used on each thickness. (a) Three-dimensional view of workpiece showing varying thickness of 640 mm (2 ft) long slab before piercing. From left to right, slab thicknesses are 38, 32, 25, 19, 13, 9.5, and 6.4 mm (1 1/2, 1 1/4, 1, 3/4, 1/2, 3/8, and 1/4 in.). (b) Top view of piece after piercing was performed. Left side is 38 mm (1 1/2 in.) section. Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island

**Fig. 11** Bending of kerf in a Plexiglas workpiece subjected to excessively high traverse cutting speeds. The portion at the bottom was pierced before cutting, and this caused a section of the hole to be eroded away as it was subsequently cut by the abrasive waterjet nozzle. Courtesy of Department of Industrial and Manufacturing Engineering, University of Rhode Island

straighten out, and then the nozzle can continue its motion.

**Work Hardening.** Abrasive waterjet machining alters the hardness of the cut surface of a number of metals. This slight work hardening is indicated in Table 4.

**Abrasive Grit Size.** Figure 14 shows how abrasive flow rates and grit number affect the depth of cut when machining cast iron. Figure 14 also indicates that neither coarse (36 and 16 grit) nor fine particles (100 and 150 grit) of garnet are the most effective abrasives. Medium abrasive of 60 and 80 grit has been found to be the most effective cutting media for a wide variety of metals.

**Pressure** is the most important parameter to be optimized in considering the depth of cut required in metals. Soft metals are insensitive to particle size but are very much affected by pressure. Figure 15 indicates the effect of increasing water pressure on 11 metals and a ceramic ( $Al_2O_3$ ).

Applications

A hand-held abrasive waterjet unit can be used, but accuracy and quality are compromised because of human instability. The abrasive nozzle must be held firmly and accurately, and the standoff of the nozzle, as well as the rate of cut, must be closely controlled. Servo-type robot arms (Fig. 16) can be programmed for point-to-point linear movements in which arcs or circles

Table 4 Effect of abrasive waterjet cutting on surface hardening of metals

Metal	Hardness(a)	
	Base	Abrasive waterjet cut
Titanium	34 HRC	34.3 HRC
Aluminum 6061-T6	54.8 HRB	58.7 HRB
Magnesium	54.1 HRB	58.4 HRB
Carbon steel A-572	82.8 HRB	84.5 HRB
Tool steel	91.5 HRB	93.3 HRB

are approximated by numerous short straight-line segments.

**Machining of Metals and Metal-Matrix Composites.** The following list summarizes the various applications for abrasive waterjet cutting:

- Job shops of various materials
- Foundries (removal of burned-in sand, cutting gates, and risers from cast parts)
- Naval and commercial shipyards (high-strength steel, lead, and so on)
- Railroad cars (manufacture and repair)
- Metal fabrication shops
- Aircraft manufacturers (titanium, Inconel, stacked metals)
- Heavy equipment manufacturers (tractors, hoists, cranes, industrial winches, derricks)
- Industrial vehicles (trucks, tankers, construction vehicles)
- Structural fabrications (bridges, skyscrapers) and heavy aluminum works
- Specialty metal fabrication (titanium, nickel alloys, chromium alloys)
- Military vehicles (tanks, armored personnel carriers, landing craft)

- Oil and gas (oil well casings, pipeline repair, platform repair)
- Mining (metal structures)

The cutting speed of the abrasive waterjet has made it a valuable tool for high-volume applications. Table 5 indicates the effect of material thickness on cutting speed for eight widely used metals and an aluminum oxide ceramic.

Abrasive waterjet cutting is also effective in fabrication of labor-intensive aircraft components, such as wingsweep fairings, upper and lower panels, bay doors, and miscellaneous bonded panels. These are large and complex parts—mostly 6.4 to 9.5 mm ( $1/4$  to  $3/8$  in.) thick and averaging 6400 to 7600 linear mm (250 to 300 in.) of periphery—that are ideally suited to a robot system capable of precision five-axis cutting over an extensive area. One example is cutting of 1.6 mm (0.063 in.) titanium using 0.68 kg/min (1.5 lb/min) of 60-grit red garnet abrasive at 300 mm/min (12 in./min). Another aerospace manufacturer has used abrasive waterjet cutting to cut through aluminum and titanium up to 64 mm (2.5 in.) thick with garnet abrasives.

Where metallurgical contamination is a concern, as in the cutting of bimetals, abrasive waterjet machining overcomes the problems of distortion, delamination, and contamination. Abrasive waterjet cutting is also cost-effective for composites. Metal-matrix composites that are cut mechanically at 25 mm/min (1 in./min) can be cut by an abrasive waterjet at 380 to 760 mm/min (15 to 30 in./min).

Figures 17 through 19 illustrate the wide variety of metals (including difficult-to-machine materials such as titanium and alloy 100) and intricate shapes (specifically the bracket shown in Fig. 18 and the turbine rotor in Fig. 19) that can be easily cut with the abrasive waterjet. The stainless steel guide bracket shown in Fig. 18 illustrates profiling around corners that would be difficult to achieve with standard machining methods. This part would require 16 or more hours to complete using conventional methods; with the abrasive waterjet, such a part can be machined within a few hours.

**Machining of Nonmetallics.** Nonmetallic materials that are readily cut by abrasive waterjet include various plastics and composite materials, such as polyurethane rubber, Styrofoam (Dow

**Fig. 18** Stainless steel aircraft guide bracket showing the profiling capabilities of the abrasive waterjet. Courtesy of Flow Systems, Inc.

Listed subsequently are some representative examples of abrasive waterjet technology used to cut nonmetallics for automotive applications:

- Trimming of thermoformed wood-fiber substrate interior door panels at speeds of 20 m/min (800 in./min)
- Finish cutting to size of 3.9 kg (8½ lb) rear door panels after initial rough cutting with more conventional methods; the panels were made of two layers of sheet molding compound coated with continuous layers of polyester resin paste and then rolled to remove trapped air.

Domestic and international electronics firms are using waterjet technology to cut the plastic laminates used in printed circuit boards. The hairlike size of the waterjet kerf and the omnidirectional, sharp cutting capabilities of the waterjet are ideally suited to the precision cutting and trimming of the boards even when they

**Fig. 19** Turbine rotor machined from a solid alloy 100 blank using an abrasive waterjet that accelerated a 60-mesh garnet abrasive at 207 MPa (30 ksi). Courtesy of Flow Systems, Inc.

are loaded with their electronic components. The absence of any lateral forces or mechanical pressure, usually associated with mechanical cutters, eliminates the board flexure that could break solder joints.

## Safety

Safety problems caused by such conditions as fire hazards and dust and noise pollution are minimized through the use of abrasive waterjet cutting, as follows:

- Safety is increased in an already hazardous atmosphere, particularly in comparison to flame and/or plasma cutting torches. Because there is no heat buildup with abrasive waterjet cutting, fire hazards are eliminated. There is no radiation emission or danger from flying slag particles.
- Airborne dust is virtually eliminated, making operation less hazardous to personnel working in close proximity to the machine. Containment or other methods of airborne dust control are unnecessary.
- Noise levels range from 85 to 95 dBA, which is consistent with Occupational Safety and Health Administration (OSHA) regulations.

# Blanking and Piercing

VARIOUS CUTTING OPERATIONS are often used to provide parts that are subsequently formed to final shape by such operations as bending, drawing, coining, and spinning. Cutting operations are frequently conducted in the same press tooling used to form and shape the final part geometry. The principal objective of any cutting operation is to produce a workpiece that has the correct geometric shape, is free of distortion, and possesses sheared edges that are of sufficient quality to allow subsequent forming, finishing, and/or handling operations. The most common group of cutting operations includes blanking, piercing, parting, shearing, notching, trimming, perforating, and so on. This article focuses on blanking and piercing operations.

## Fundamentals of Cutting

In blanking, piercing, and related cutting operations (such as trimming, notching, parting, and so on), the metal is stressed in shear between approaching cutting edges until a fracture occurs. It is desirable to estimate the maximum blanking or shearing pressure required for the various tools, the effect of this maximum pressure or shear on the punch or die (grinding of one or the other at an angle), and the power and flywheel energy needed for the work.

If the tools are ground flat and parallel and friction on the punch and die is neglected, the maximum pressure required to blank out a punching is normally the product of the shear strength of the metal and the cross-sectional area around the periphery of the blank. Thus, the formula for maximum pressure ( $P$ ) is:

$$P = L \times t \times S, \text{ or } P = \pi D \times t \times S \quad (\text{Eq 1})$$

where  $S$  is the shear strength of the material,  $t$  is the sheet thickness, and  $L$  is the length of the cut or the periphery of the blank. If the blank is round,  $L$  may be replaced by  $D$ , which is the diameter of the punching (or the sum of several diameters). Figure 1 is a nomograph derived from the aforementioned formula, with its limits selected to cover the normal range of power-press (and squaring-shear) capacities. An example is shown in dashed lines. The shear-strength values indicated at the left in the chart depend, of course, on material condition and prior processing.

As a flat punch progresses through a sheet of metal, it deforms the metal plastically to a point

**Fig. 1** Chart (derived from Eq 1) for determining blanking pressure to cover the normal range of power-press (and squaring-shear) capacities. In reading this chart, lay a straightedge or ruler on the chart so that it connects the desired values of metal thickness with the length of cut ( $L$ ) or the diameter ( $D$ ) for cutting a round. Mark or note the point where it crosses the centerline. Move the straightedge to connect this point on the centerline with the proper value for the shearing strength of the metal to be cut. The line through these two points crosses the shearing-pressure line at the tonnage required to punch the blank or hole. The shear-strength values indicated at the left depend on material condition and prior processing.

where the ultimate strength is exceeded, and fractures start from the opposing cutting edges of the punch and die (Fig. 2). If there is proper clearance between the tools, the fractures meet almost instantly, and the fractured portion of the sheared edge appears quite clean. If the clearance is not sufficient, the first fractures do not meet, and secondary shearing takes place, with a characteristically irregular and ragged appearance around the edge. When the cut is clean, a brightly burnished band around the edge of the blank indicates how far the punch had to penetrate before the fracture occurred. This is of interest in connection with Fig. 3 and 4, because the work is entirely or nearly completed at this point.

Figure 5 illustrates diagrammatically the effect of shear on the blanking load. The term *shear*, as used here, refers to grinding either the punch or the die at an angle, the other member remaining flat so as not to distort the product. The amount of shear is the difference between the high and low points of the angular face, even though the punch may be ground down both ways from one or more high points.

The effect of shear is clearly to reduce the peak load of blanking by shearing a little work metal at a time instead of making the whole cut at once. The total energy required to do the job is not changed, being merely that a lower pressure is continued for a longer time. A small amount of shear (less than the distance a flat punch must

travel to effect shearing) does not appreciably reduce the load but does ease the snapback, especially of C-frame presses, which occurs when the whole load is released instantly by the fracture.

Figure 3 is designed for use in approximating the extent to which the total or maximum load is reduced by shear on the tools. In the case of ample clearance and a clean fracture, the result obtained is high, because the calculation is based on the assumption that the working pressure without shear is equal to the maximum pressure recorded, throughout the working distance. Actually, however, the pressure rises gradually to the maximum and then usually falls somewhat to the point at which fracture occurs. The average pressure for the penetration distance, which would naturally be lower than the maximum pressure, would give an accurate result. An accurate pressure diagram is rarely available,

and the chart in Fig. 3 is close enough for ordinary purposes. Note that it is always desirable to have considerable excess press capacity for blanking work, for the sake of the tools.

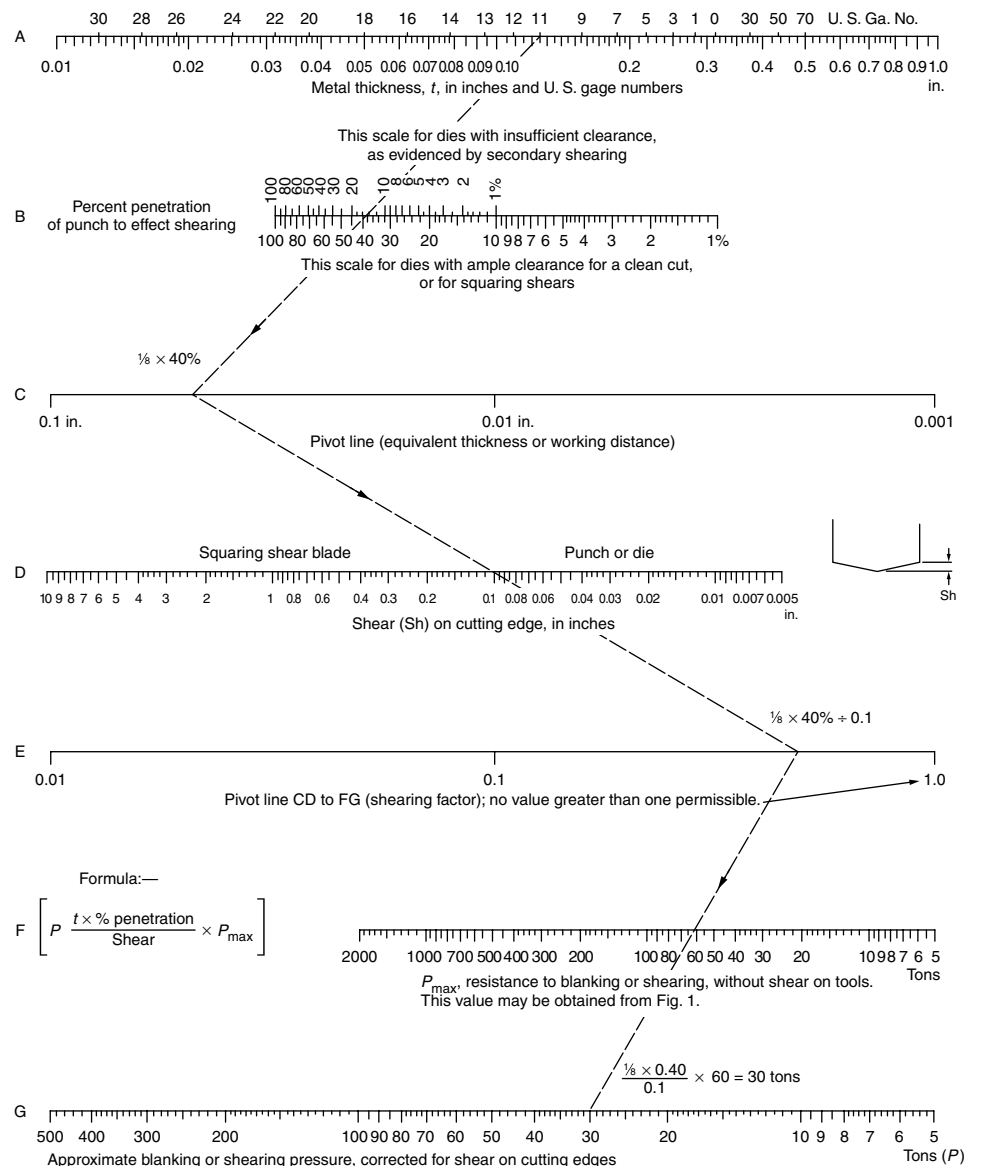

In the case of insufficient clearance in the tools and a ragged fracture, secondary shearing occurs so that the pressure curve does not drop sharply. The amount of secondary shearing increases as the clearance becomes less and less. The square-root scale for percent penetration is an arbitrary method of compensating for the effect of secondary shearing but is ample for ordinary cases. In many cases, of course, the result will be high.

Figure 3 is read from the top down, and, as indicated by the example in dashed lines, the third and fifth lines are used only as pivot points for the straightedge. The formula is:

$$P = \left( \frac{t \times \% \text{ penetration}}{\text{Amount of shear}} \right) \times P_{\max} \quad (\text{Eq } 2)$$

**Fig. 2** Progress of a punch through sheet metal, showing plastic deformation and fracture. A, B, and C show ductile metal with ample clearance. D, E, and F show similar metal with insufficient clearance. G and H show hard metal with sufficient clearance. I shows the effect of dull cutting edges.

**Fig. 3** Chart for determining effect of angular shear

The thickness multiplied by the percent penetration to effect shearing gives the actual working distance in inches. This value divided by the amount of shear on the tools, in inches, gives the proportion of the length of the cutting edge that is actually working at any instant (Fig. 5). This value multiplied by the maximum pressure (without shear) from Fig. 1 gives the approximate maximum working pressure.

In checking power requirements of flywheel capacities, it is necessary to know the actual energy absorbed in doing the work. In the case of shearing, this is properly the working distance multiplied by the average pressure, or, graphically, the area under the pressure-distance curve. Because such curves are not easily obtained and therefore average pressure cannot be measured, the approximate methods used previously are once again employed. Thus, in Fig. 4, the max-

imum pressure ( $P$ , from Fig. 1) is used in place of average pressure, and the working distance is taken as the product of the metal thickness,  $t$ , and the percent penetration, using two scales for the latter. Then, the energy or work,  $W$ , in inch-tons is:

$$W = T \times \% \text{ penetration} \times P \times 1.16 \quad (\text{Eq 3})$$

The 1.16 adds a 16% allowance for machine friction. This can only be a general case, of course, because the arrangement and condition of machines vary widely.

It should also be noted that an allowance should be made for heavy stripper springs, when used, and for wall friction in pushing slugs through the dies when there are long straight walls, as is occasionally the case.

In using Fig. 4, read thickness and percent penetration first, to obtain the pivot point for the

straightedge. Then, set the straightedge to connect this point and the pressure value, to obtain the energy requirement.

## Blanking Operations

Blanking is the process of cutting or shearing, from sheet-metal stock, a piece of metal of predetermined contour to prepare it for subsequent operations. The piece of metal resulting from this operation is commonly called a blank. The prime objective in planning a blanking operation is to select a blank that will produce a part of prescribed quality, within reasonable cost, that can be produced in the quantity required to maintain production schedules. The blank must be designed to provide enough metal to shape the part and, at the same time, prevent excessive scrap loss due to trimming.

The design of the blank also depends on the desired part and the subsequent method of forming. For example, when a part is drawn, deformation occurs over a major portion of its surface. The metal flows and bends and sometimes stretches. To accomplish this severe deformation, the metal must be held around the edges to prevent wrinkling and tearing. In contrast, deformation during bending is usually confined to the area immediately adjacent to a bend line without the metal flowing or stretching. In this case, a blank may be laid out for bending without the necessity of trimming. In the design of the blank for a drawn part, however, metal must be provided at proper places to permit the part to be shaped to specifications. Metal also must be provided for holding.

Fig. 4 Chart for determining energy required in shearing

Fig. 5 Effect of shear ( $Sh$ ) on blanking load. Different angles of shear on the punch (or die) reduce the amount of work it is doing at any instant.

The types of blanks used in sheet-forming operations fall into four convenient classifications. These classifications are rectangular blanks, rough blanks, partially developed blanks, and fully developed blanks (Fig. 6 and Table 1). This classification of blanks has permitted the application of some general rules to follow in setting up the blanking operation for a part. These rules deal with the type of a blank that should be used for a given type of part, the form of material from which the blanks should be cut, and the method and equipment that should be used in making the blank.

### Rectangular Blanks

A rectangular blank is the least complex type of blank and the easiest to produce. As its name implies, it is rectangular in shape, having four straight sides. Its size is determined by the amount of metal required in the part and the amount of metal needed for trim allowances and holding. Rectangular blanks are usually restricted to production of drawn parts, although it would be possible to produce symmetrical, simple channeled formed parts from such blanks.

Only a portion of a rectangular blank appears in the finished part, because the outer edges of the blank provide surfaces for holding during drawing and are trimmed away. A fuel-tank half for an automobile is an example of a part made from a rectangular blank.

**Why Rectangular Blanks Are Used.** While the rectangular blank is somewhat limited in its application to various types of parts, certain definite advantages can be obtained through its use. These advantages result primarily from the type of equipment used in making rectangular blanks.

A squaring shear is the most prominent type of equipment used in making rectangular blanks. This machine consists of an appropriate frame and a moving cutting blade that acts on metal positioned over a lower cutting edge. A blank is produced at each stroke of the blade, which can be adjusted to operate at a very high speed. Thus, a rectangular blank can be produced at a high rate of speed. In addition, a squaring shear can be set up with automatic feed and cutoff, resulting in a very low direct labor cost per piece.

The squaring shear can be adjusted to accommodate blanks of varying length with very

little difficulty. A wide range of blank widths also can be accommodated. The ease of adjustment of the squaring shear makes it a very versatile machine. This makes rectangular blanks advantageous, because very little time is involved in setting up for their production.

One of the chief advantages of the rectangular blank is that no die is required. This results in a very considerable savings in the cost of establishing a blanking operation.

One of the unfavorable aspects of the rectangular blank is the large amount of waste material that results from its use. Except in the case of a rectangular-shaped part, such as a gas tank, a sizeable portion of a rectangular blank is lost to immediate production in the form of unusable scrap. On low-production jobs, the scrap loss is often offset by a reduction in die costs. In other jobs, however, especially high-production jobs, scrap loss is often one of the most important factors. For this reason, the choice of a rectangular blank should be weighted carefully in terms of the cost of scrap and its relation to the savings possible through use of the square-shearing method.

**Materials Used in Making Rectangular Blanks.** The form of material used in producing rectangular blanks is an important consideration in setting up blanking operations. Two forms of material are generally used: sheet stock and coil stock (Fig. 7 and 8).

Sheet stock may be used for producing rectangular blanks for low-, medium-, and high-volume requirements. Where this form of stock is used, manual operation of the squaring shear is usually involved. A package of sheets is delivered to the squaring shear by crane or lift truck.

Fig. 6 Types of blanks

Fig. 7 Preferred sizes for ordering sheet stock

Table 1 Summary of application of blank types for different blanking methods

Type of blank to be produced	Blanking method			
	Squaring shear	Push-through blanking die	Compound blanking and piercing die	Pierce, notch, and cutoff die
Rectangular blank	Good	Poor	Poor	Poor
Rough blank	Good. For straight-side symmetrical blanks; unsuitable for blanks with curved edges	Fair. For small parts only	Fair. For small parts only	Good. For small and large parts
Partially developed blank	Poor	Fair	Good. For small and large parts and parts with holes that can be pierced before drawing or forming	Good. For small and large parts and parts with holes that can be pierced before forming
Fully developed blank	Poor	Good. For small parts that do not require holes	Good. For large parts and those requiring holes	Fair. Precision sizing usually not obtainable with notch-and-cutoff die

Each sheet is removed from the bundle and fed manually to the shear, where it is cut to a predetermined layout.

Using the proper size of sheet for making blanks is important from the standpoint of material cost. First, a sheet should be of a size that will yield the most blanks with minimum scrap loss. A no-scrap layout is most desirable.

Second, the size of the sheet should be planned with consideration of the variations in steel prices that are based on width and length of sheet. The most economical sizes of hot rolled low-carbon steel sheet range from 0.9 to 1.2 m (36 to 48 in.) in width and from 2.3 to 4.9 m (90 $\frac{1}{16}$  to 192 in.) in length. For cold rolled low-carbon sheet, the economical range of widths is the same as for hot rolled sheet. The length range, however, is from 1.5 to 4.6 m (60 $\frac{1}{16}$  to 180 in.). The purchase price for sheet outside these size ranges is greater because of additional operations required at the steel plant. Narrower sheet must be supplied by adjusting the mills or by slitting wider sheet. Greater widths require special adjustment of the reducing mills. Lengths outside the economy-sized range cost more because of the increased effort involved in operating the flying shear that is used to cut the sheet.

Coil stock, when used, should also be ordered with consideration of the relation of price to size. Ordinarily, coil length does not affect price. Width, however, does, and the most economical width range is from 0.9 to 1.2 m (36 to 48 in.).

Coil stock is used for producing rectangular blanks for high-volume requirements. The coil is delivered by crane and clamped between the arbors of an uncoiling machine. The coil is passed to the shear automatically through feed rolls. The stock advances to a stop on the back of the shear, and the cut is made by the blade, which is automatically activated by a limit switch. This type of operation is very economical from the standpoint of direct labor costs, because manual handling is greatly reduced and production is greater.

### Rough Blanks

A rough blank is a workpiece cut roughly to the size and general contour of the finished part

Fig. 8 Preferred sizes for ordering coil stock

but having a margin of extra metal completely around the trim line. This extra metal is supplied for holding in subsequent operations and is cut off in the trim operation. A rough blank may be cut in a number of shapes. It may have straight sides and be in the shape of a triangle, diamond, trapezoid, hexagon, octagon, or even a "T." It also may have a combination of straight and contoured sides, giving it a nonsymmetrical shape conforming to no particular shape classification.

Rough blanks are used for making drawn parts. The surplus metal outside the trim line permits the binder surface of the die and the blankholder to restrain the edges of the blank for desired metal flow and/or stretching action. In rare instances, a rough blank may be used for a formed part that presents difficult metal-holding problems, such as a part with a difficult contoured flange.

**Why Rough Blanks Are Used.** The chief purpose of using rough blanks is to obtain material economy. As compared with rectangular blanks, rough blanks achieve this purpose very well. Because the blank conforms roughly to the shape of the part, less metal is trimmed away as scrap. A rough blank, properly nested, will also require less metal per piece than a comparable rectangular blank. ("Nesting" refers to the layout of the blank in the sheet or coil stock.)

Another advantage of rough blanks is that they generally can be handled more easily through successive operations than can rectangular blanks. The binder surface of a rough blank is generally smaller, and it is usually free from extended protruding corners. This permits easier loading of the part in operations subsequent to the initial draw and reduces the hazard of protruding corners being struck against press or handling machines.

**How Rough Blanks Are Made.** Depending on the needs of the situation, one of two methods may be used in making a rough blank. For blanks having symmetrical shapes and straight edges, such as triangular, diamond-shaped, and trapezoidal blanks, the squaring shear may be used. For nonsymmetrical parts, presses are used with dies of the cutoff type. These dies are sometimes called progressive blanking dies.

Fig. 9 Plain cutoff die

A plain cutoff die (Fig. 9) cuts the blank in two or more steps in a manner similar to the squaring shear. The die set includes upper and lower shearing steels. In operation, the stock is moved forward to a predetermined stop, the press is cycled, and the part is cut off. Each cut creates the final edge of one blank and the initial edge of another blank. One of the principal differences between a progressive cutoff die with a die and press and a squaring shear is that the cutoff die often produces an irregular cut, while the squaring shear always cuts on a straight line with simple shear blades.

The cutoff die is often used to produce two blanks simultaneously. This is made possible by incorporating two sets of cutting steels in the die. When this method is employed, one blank may be ejected off the end of the die and the other off the side of the die for effective disposal. Feeding must be arranged to advance the coil or strip as required.

The notch-and-cutoff die is also used for making rough blanks. This die is similar in operation to the plain cutoff die. However, two separate work stations are incorporated in the notch-and-cutoff die. In the initial work station, notching punches are mounted on the upper shoe with mating die sections on the lower shoe. These punches may be designed to notch triangles, semicircles, and many other blank-edge shapes that would be difficult or impossible to produce in a cutoff die alone. The notching tools provide only a part of the shape of a blank's edges; the remainder of the shape is supplied by the cutoff tools. The cutoff takes place in the last work station. The cutoff tool is usually lined up with the apex of the notch to ensure a clean cut.

Pierce, notch, and cutoff dies (Fig. 10) are used in some cases for producing rough blanks for formed parts. The major characteristics of this type of die are discussed in relation to developed blanks.

The presses used for the foregoing progressive-type blanking operations are usually of the gap-frame inclinable variety for easy feeding of stock and quick disposal of blanks. For some large blanks, such as for fenders and quarter panels, where pressure requirements warrant, large presses of the straight-side type are used.

**Materials Used in Making Rough Blanks.** The principles cited for selecting an economical form of material for making rectangular blanks apply equally to rough blanks. In fact, rough

Fig. 10 Pierce, notch, and cutoff die

blanks require special consideration of layout for material economy. Because rough blanks are often nonsymmetrical, they must be planned and designed carefully to achieve material economy. The choice of strip or coil stock should be made with a view toward volume requirements and the reduction of offal (Fig. 11).

### Developed Blanks

A developed blank may be described as a blank of any shape, symmetrical or non-symmetrical, that is precision sized so that no trimming is required after the part has been shaped. Developed blanks are used almost exclusively for parts that are formed. Practically all stampings used in chassis frame construction are in this category, as well as many internal parts of automobile bodies and front-end assemblies (Fig. 12).

**Why Developed Blanks Are Used.** Developed blanks offer greater opportunities for savings in material and operating costs than any other type of blank used in stamping operations. There is no scrap resulting from trimming, and the need for expensive trim dies is avoided, where developed blanks can be used. Developed blanks cannot be used for drawn parts because of the requirement for extra metal for holding purposes in drawing.

Some scrap does result when developed blanks are used. This scrap is generated when the blank is cut from the parent stock. However, by proper nesting, scrap can be minimized. The scrap can also be used in production of blanks for small parts.

**How Developed Blanks Are Made.** A developed blank having mainly contoured edges is made in a push-through blanking die mounted in a suitable press. One advantage of this type of setup is the ease with which disposal of the blank is accomplished. The blank is merely pushed through an opening in the lower die shoe and the press bolster to a container below. In some instances, the blank is allowed to fall onto a conveyor that then carries it to a subsequent operation.

A push-through blanking die (Fig. 13) may be defined as one in which a sheet of metal to be cut is laid over a sharp-edged die opening, and a punch, with cutting edges to fit the die, is forced through the sheet metal into the die opening.

The punch assembly consists of a tool steel punch and a stripper mounted on a shoe with guide bushings. The stripper is provided to remove the scrap from the punch on the upstroke of the press.

The die assembly consists of a conventional die shoe that is equipped with guide pins to ensure accurate alignment. The guide pins are important in making a developed blank because of the precision sizing necessary. Careful alignment is also necessary to prevent damage to cutting steels. Additional components of the push-through die are the composite steels that comprise the cutting edges, backing plates, and stock guides.

Push-through dies are not considered practical for punching out blanks for large parts, because a large die opening would allow the stock to sag and become distorted before the cut was made.

For low- or medium-volume work, a single push-through blanking die may be used with offal or sheet stock hand fed to the die. For high-volume work, double dies are often used to make two blanks, either separate or connected, with each stroke of the press. In some cases, dies for two different parts may be used in the same press at the same time. Coil stock and automatic feed mechanisms are usually used when production requirements are high.

A developed blank may also be made in dies other than the push-through type. These dies are the compound blanking and piercing die, and the notch, pierce, and cutoff die.

The compound blanking and piercing die (Fig. 14) performs more than one operation. Both blanking and piercing are completed in one stroke of the press and in one station in the die. The compound blanking die is situated in an upside-down position, with the sized cutting section on the upper shoe. This upside-down position provides support for large parts to prevent buckling or sagging, permitting large

developed blanks to be made. However, many small developed blanks are also produced in this type of die.

Combining piercing and blanking in one operation enhances the economy of a press operation. However, care should be taken that holes pierced will not become undesirably deformed in later forming operations.

The important parts of the punch assembly are the die section, the piercing-punch assembly, the stripper, and the knockout pad or pin.

The principal components of the die assembly are the tool steel punch and the stripper. The punch includes die buttons for receiving the piercing punches that are mounted on the upper shoe.

The actions that take place in a blanking and piercing die may occur simultaneously or in sequence. Piercing usually occurs first, because the metal can be held more firmly before blanking takes place. In some cases, however,

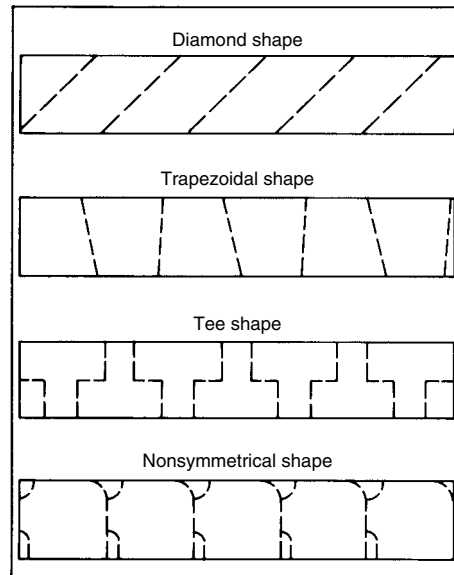

Fig. 11 Layouts for rough blanks

Fig. 12 Layouts for developed blanks

Fig. 13 Push-through blanking die

the blanking may be done first, with the face of the punch being used to hold the material while piercing takes place.

The notch, pierce, and cutoff die can also be used for producing a developed blank for a forming operation. This die is a modification of the progressive blanking die and includes the piercing function where holes produced will not be distorted in later forming operations.

Presses used in making developed blanks come in a range of sizes proportionate to the size of the blank being made. Most are of the straight-side type to ensure accurate alignment of cutting steels.

**Materials Used in Making Developed Blanks.** In making a developed blank, the choice of the form of material to be used is a highly important factor. The choice will be influenced by the size of the blank and the production volume of the part.

Offal stock is used for small, low-volume parts, that is, where requirements per 16 h day are less than 1400 parts. Offal is restricted to such work because of the difficulty in handling the unevenly shaped pieces. It is used only with blanking and piercing, blanking and forming, or push-through blanking dies. The progressive type of die cannot use offal for blanks because of difficulties in moving the part through such a die. The use of offal in all possible applications is desirable from the standpoint of material economy but must be analyzed very closely.

Sheet stock is used for low-volume work, and for medium-volume work where the requirements are from 1400 to 2000 parts per 16 h day, or for large parts. All sizes of blanks may be cut from this type of material. It may be used in push-through blanking dies or in compound blanking and piercing dies. It can also be used in progressive blanking dies. Heavy-gage sheet stock is used for high-volume work where requirements are over 2000 per day, because such metal is of too-heavy gage, and coils would be too short. Stock of this type is used for making generator frames, chassis frame parts, and other heavy-duty applications.

Coil stock may be used for medium-volume work in a push-through, blanking and piercing, or progressive blanking die. Coil stock is used on all high-production stampings whenever it is practical to secure and use it in such form.

The layout of material for a developed blank is another important aspect of establishing an effective operation. The form of a developed blank is usually complex, and nesting it economically in a sheet or coil is sometimes more difficult than for a rectangular or rough blank.

One method of arriving at economical nesting is to prepare several paper templates of blank and place them on the stock. By shifting them around on the stock, the nesting that results in the least scrap may be determined.

If, in using strip stock, two nestings show equal promise, it may be necessary to lay out the entire strip to determine which nesting will yield the least scrap at the beginning and end of the strip. End scrap is less important when coil stock is used, because of the greater length of material. The method selected for cutting the blanks from strip or coil may also provide means for material economy. By feeding a strip through the die twice, it may be possible to obtain blanks from the scrap left after the first pass. Blanking in multiples (cutting more than one blank at a time) may offer additional material savings. It is generally practical to blank multiples from the widest stock possible. It is easier to feed wide strips of short multiples than it is to feed narrow strips of long multiples. Use of excessively wide strips must be avoided to escape payment of premium steel prices.

One method of determining the best nesting arrangement among several choices is to calculate the total area of stock required in square inches, to produce each piece. The scrap involved is included in the calculation. To determine the area for each piece from a given layout, multiply the distance between the centers of two blanks by the width of the strip. A comparison of the figures obtained from analyzing several nesting possibilities by this method will readily reveal the best course to follow.

Certain basic rules in blank development for push-through die work should be followed in order to ensure production of blanks having clean-cut edges. These rules pertain to the amount of scrap that should be left between developed blanks to ensure a clean cut. For stock lighter than 11 gage, at least 3.2 mm ( $1/8$  in.) of stock should be allowed between the blanks and at the edge of the stock. For stock of 11 gage or heavier, at least 4.8 mm ( $3/16$  in.) of stock should be allowed for scrap. This scrap allowance is necessary for a clean cut and to prevent the edges of the blank from being pinched to a sharp edge or being drawn down into an excessive burr. Sometimes, where edge conditions are less important and blanks are fairly symmetrical, no scrap allowance is necessary. If such is the case, blanks may be laid out adjoining one another.

In some cases, the grain direction of the metal may be a factor in laying out blanks. This factor is prevalent in electric-furnace and bessemer steels. There is no appreciable grain direction in open-hearth steel. Where definite grain direction does exist, however, blanks for forming operations should be cut in such a way that bends will be made across the grain by at least  $30^\circ$ . Bends made parallel with the grain direction will cause fractures at the radius of the bend.

Balancing the cuts in blanking operations is another important factor in ensuring effective blanking operations. Where cuts are unbalanced, shifting of the cutting steels is apt to take place. This will result in malformed blanks and excessive wear on cutting tools. This problem may be overcome, in some instances, by cutting blanks two at a time. The two unbalanced cutting edges will offset one another to create a balanced condition.

Wherever possible, blanking operations should be set up so as to safeguard the ease with which subsequent operations can be accomplished. This again may call for blanking of two parts at a time and leaving them fastened together to provide balanced conditions in forming or piercing operations that follow.

### Partially Developed Blanks

A partially developed blank (Fig. 15) is defined as a blank that is precision sized on two opposite sides of a part, with the remaining two sides providing excess metal for holding purposes. This type of blank is used for drawing of parts where holding is required on only two sides. Roof rails are typical parts for which partially developed blanks may be used. There are only a few automotive stampings of this type, and hence, partially developed blanks are rarely used. Where they are used, however, the complexity of trimming is slightly reduced.

A partially developed blank is usually made on a cutoff die, a notch-and-cutoff die, or a compound blanking die.

The general rules for selecting forms of material for partially developed blanks correspond to those cited for developed blanks.

Fig. 14 Blanking and piercing die

## Blanking Clearances and Shear

Certain mechanical problems that arise in cutting of metals also must be considered in establishing blanking operations. These mechanical problems include clearances between cutting steels and the pressure requirements for performing the shearing operation.

**Clearances.** In blanking, the die steels are built to the dimensional specifications of the blank, and any clearance required is machined on the punch. Clearances must be sufficient to avoid secondary shearing and close enough to prevent excessive burrs and deformation of blank edges. Pressure requirements for blanking are also affected by clearance. Usually, the greater the clearance provided, the less the required pressure. For best quality in blank edges, cutting tools should be kept sharp.

**Shear** is ground on the die section in blanking operations. The sheet metal in a stamping operation always assumes the shape of the punch. Hence, if the shear were on the punch, the blank would be deformed. By providing shear on the die, the blank is produced flat, and the scrap is deformed.

Shear is provided to reduce pressure requirements by permitting the cut to be made a little at a time. Shear provides the additional benefit of facilitating accurate blanking, because the reduction in pressure reduces the chances of distorting the part. Balanced or unbalanced shear may be provided, depending on the cut to be made and the precision required in the part.

## Piercing Operations

Production of a sheet-metal stamping requires application of a variety of types of stamping operations. In the preparatory stages, blanking is used to cut out a workpiece of proper design and with sufficient metal to yield the desired part. This workpiece, or blank, is forced to assume the required shape by means of a forming or drawing operation. The specified edge dimensions of the part are obtained either in the blanking operation or in a trimming operation. However, in nearly all cases, a stamping requires more than sizing and shaping operations before it becomes a finished part. Holes, slots, tabs, or notches are incorporated in the part to bring it into conformity with specifications. The creation of holes

or openings in sheet metal is done by the process of piercing.

Pierced holes serve many important purposes in the overall design and use of a part. They provide means of fastening the part to other components of an assembly and sometimes provide means of making a component lighter in weight. They serve as locating points to facilitate subsequent stamping operations and provide access to oil holes, drain plugs, and other parts through firewalls and other panels of the car.

Although piercing is regarded as one of the least complex of stamping operations, the establishment of successful piercing operations requires careful planning by the process engineer. The great extent to which piercing is employed is, in itself, enough to support this conclusion. In addition, tools must be provided that will prevent excessive cost due to breakage. A good deal of standardization in tooling is called for. Operational sequences must be established properly in order to prevent deformation of pierced holes and the production of defective parts. In short, the success of a total stamping process is equally as dependent on efficient piercing operations as it is on other types of operations.

## Types of Piercing Operations

The various types of piercing operations employed in metal stamping (Fig. 16) derive their names from the kind of hole or cut that is to be made. Each of these holes or cuts is designed to accomplish a specific purpose in the design or use of the part.

**Conventional piercing** usually consists of driving a round flat-face punch through the part into a die section or button. The portion of metal under the punch is totally removed from the part. This piece of metal is called a slug. The resulting hole is normally used as a means of fastening parts together with rivets, bolts, or screws.

The majority of piercing operations are of this type, and the holes so produced cover a broad range of sizes. As a result, punches of various sizes are necessary to provide the tools required to meet piercing needs. This range of punch sizes has been modified by the application of punch-sized standards. Care should always be taken to provide a standard-size punch wherever possible.

**Piercing with a Pointed Punch.** Another operation commonly referred to as piercing is the creation of a hole with a pointed or cone-shaped punch. In this type of operation, no slug is removed. The hole results from a pushing apart and extrusion of the metal as the punch passes through it. This results in an extruded collar around the hole. The edges of this collar are ragged because of the nature of the break that takes place. The collar is sometimes tapped to provide a means of fastening another part with a bolt.

**Pierce-and-extrude operations** consist of first punching a hole in the part and then extruding the edges of the hole to provide a circular flange around the enlarged hole. This operation calls for a punch of special design and special features in the die set. The end of the punch is flat, to break out the slug, and a beveled shoulder higher on the punch extrudes the hole edge and enlarges the hole as the punch passes through. Because the hole has been cut larger by the punch end, the edges of the extruded portion are cleaner and freer from cracks than in the case of the pointed punch. However, a certain amount of raggedness exists. Where a very smooth edge is needed, the hole may be reamed before extrusion. Extruded holes of this type may be used to provide spacing between panels; they may be used for strengthening holes in parts (such as hinges) that are mounted on rods or bolts; or they may be used as bosses or locators on which to mount other parts.

**Slotting** is used to provide holes of special shape (that is, noncircular), such as elliptical holes or rectangular holes. These holes may be required on some parts to allow for adjustment of the fit of a part in an assembly. A slotting punch requires a special design. The cutting portion must be shaped in accordance with the shape of the hole to be produced.

**Countersinking** is also done with the use of a special punch. This punch is similar to that used in piercing and extruding. In countersinking, however, the distance the punch travels through the stock is less than in extruding. The punch is driven far enough to create a hole and a tapered flange around the hole. This depressed hole is used where the head of an assembly bolt or screw must be flush with or below the surface of the part.

**Cutting and Lancing of Tabs.** In cutting and lancing of tabs, the tab is usually the item of importance rather than the resulting hole. The tab is created by a punch that cuts all but one side of the opening produced, leaving the tab attached to the part. The operation consists of shearing a U-shaped, V-shaped, or rectangular cut in the metal and pushing the tab downward with an unsharpened edge of the punch. The tab may be used to locate the part for later processing or to facilitate fitting of the part in an assembly.

## Tools for Piercing

In a broad sense, the principal components of a set of piercing tools are the punch, the die, and

Fig. 15 Layouts for partially developed blanks

Fig. 16 Types of piercing operations

the stripper. The punch creates a hole as it is forced through the material. The die consists of a steel block in which a hole matching the contours of the punch is provided. The edges of the hole provide the lower cutting edge and cooperate with the punch in shearing the material. The slug from the material usually drops through the hole in the die. The stripper consists of a plate with a suitable hole through which the punch point passes. It has a dual function in that it holds the material from slipping during piercing and keeps on holding it so as to strip the material from the punch as the punch retracts. The tool setup functions in the following manner. The stripper descends to hold the stock against the face of the die. The punch follows through the hole provided in the stripper and is forced through the material into the die hole. On the upstroke, the stripper dwells and holds the material as the punch is withdrawn. The material must be held in this manner because it tends to cling to the punch surface. After the material is stripped from the punch, the stripper plate rises, allowing the part to be removed.

The foregoing description of the makeup and function of the piercing die is couched in the most general terms. Actually, many more factors are involved. The tools are generally much more complicated, the degree of complication depending on the operation involved.

**Punch Assembly.** Actually, the term *punch* may refer to two different items in considering a piercing die setup. It may refer to a single tool for creating a hole, or it may refer collectively to an assemblage of components that may create several holes and even perform other operations.

The base for building a punch assembly is the upper shoe. This may be made from a mild steel plate, or it may be a casting. All other punch components are fastened to the shoe. Bushings should be provided in all shoes for guide pins to ensure accurate tool travel.

Hardened steel backup plates are attached to the shoe in areas where the individual punches will be placed. This is necessary to prevent the bases of the punches from being driven into the softer metal of the shoe during operation.

Another component of the punch assembly is the punch retainer. This is a device for holding the punch. Standards have been developed for types of retainers to be used with standard punches. A standard retainer is used whenever possible. In some cases, where there is insufficient space, or where several punches are necessarily mounted in a small area, special retainers may have to be used.

The working end of the punch assembly consists of the individual punches. These are held in the punch retainers by several means. The method of holding may depend on the size and shape of the punch and whether it is used singly or in combination with other punches. The service for which the punch is to be used also influences the holding method. For piercing heavy material, a more positive holding method is required than for piercing light material. This is true because of the heavy stripping load that

exists in piercing heavy material. For an operation in which numerous parts are to be pierced, the holding system may be more elaborate and expensive than in an operation where total production quantity is low.

For high-production jobs, the ball-seat holding method may be employed. This system provides for the rapid changing of punches, an item of considerable importance in high-volume operations. In some cases, the stripping pressure may require the use of a shoulder-type holding system. In other cases, bridge-lock or solid-type holding may be best (Fig. 17).

To accommodate the various types of piercing operations, a variety of piercing punches have been developed. Each type has certain special characteristics that make it suitable for the job to which it is applied.

The most widely used type of punch is called the regular-duty punch. It is generally round in shape and is mass produced by a number of tool manufacturing companies. Its simple design and its abundance make it relatively inexpensive. It is of the ball-seat type and thus presents a minimum problem with relation to downtime for changing tools. It is used for making holes up to 25 mm (1 in.) in diameter when the stock thickness is 3 mm (0.12 in.) or less.

For stock that is thicker than 3 mm (0.12 in.), and for holes 25 to 38 mm (1 to 1½ in.) in diameter, a shoulder-type punch is used. The heavier construction of this type of punch provides the added strength necessary to ensure reasonable tool life in this heavier type of work. The shoulder punch also permits a stronger holding method to resist the greater stripping pressure that exists where larger holes or thicker stock is involved.

A solid-type punch is used for piercing holes over 38 mm (1½ in.) in diameter. This type of punch is very heavily constructed and is bolted directly through the backing plate to the upper shoe.

Normally, piercing is confined to production of holes that are greater in diameter than the thickness of the stock involved. This is because piercing of holes with diameters less than stock thickness results in excessive breakage of punches, unless special strengthening provisions are

made in the punch. A punch thin enough to pierce a very small hole will not withstand the forces required to shear the stock on a sustained basis, unless it is sufficiently reinforced. Thin punches tend to deflect or whip on contact with the stock, adding the probability of breakage. The reinforcement provided to enable such piercing to be done consists of several elements. The point of the punch is made as short as possible; the main body of the punch is made large and is brought as close to the point as possible; and a die-cast soft metal sleeve is pressure cast to the punch to absorb the whipping and deflecting forces. This cast sleeve is called a whipsleeve, and punches so constructed are called whipsleeve punches (Fig. 18).

Whipsleeve punches are used for piercing holes where the metal thickness exceeds the punch diameter. They are also used in producing slightly larger holes where whipping and deflection are a problem.

A quill punch (Fig. 18) may also be used to pierce holes smaller than stock thickness. This punch has a very short point and is encased in tool steel for strength. Hard stock may also be pierced with this type of punch.

A large number of special punches are used to create special types and shapes of holes.

A blade-type punch is used for piercing long, narrow slots. It consists of a steel blade mounted in a special retainer.

Another special type of hole is made by the presthole punch (Fig. 18). This punch is designed to pierce out a small amount of stock, countersink the edge of the resulting hole, and slit the countersunk edge. This provides a gripping device into which a screw or bolt can be assembled without using a backing nut.

Another special type of operation is accomplished by the use of a developed punch. This punch is used to create round holes in stock held at an angle, although the punch travel is vertical. To accomplish this, the punch point is ground into an oval shape.

**Die Assembly.** The die section of the piercing-tool setup is also an assembly of several components. It generally consists of a lower shoe, die sections, die buttons, guide pins, and chutes or trays for the elimination of punched-out slugs.

Fig. 17 Punch-retaining methods

Fig. 18 Special punches

The lower shoe, or die shoe, is a mild steel plate or a casting to which all die components are fastened. Guide pins are fastened to the shoe and are used to ensure accurate travel of the punch. Heel blocks are often added to absorb any tendency of the punch to deflect during the work stroke.

The die sections in a piercing setup usually perform the function of holders for the die buttons. In some cases, the die sections are drilled through and hardened to provide opposing cutting edges for the punch. This practice is usually not followed because of the simpler die maintenance achieved through use of die buttons.

A die button is a hardened steel cylinder with a hole designed to provide opposing cutting edges for a punch. The hole of a die button will conform to the shape of the punch with which it is used. Die buttons, like punches, are available in many standard sizes. Special die buttons are also available for use with punches of special design.

In establishing any piercing operation, consideration should be given to the elimination of slugs from the die. Slug chutes should be provided in the die to move the slugs to convenient accumulation points. In some cases, slug trays should be incorporated in the die to prevent the slugs from piling up on the floor under the press. Where slug trays are not used, adequate receptacles should be provided at the accumulation point.

**Stripper.** After the punch has penetrated the metal, it must be pulled back. Because of elasticity, the metal compressed at the beginning of piercing tends to expand and grip the sides of the punch. This gripping causes the pierced part to rise with the punch. Thus, a mechanism must be provided to hold the part down while the punch is withdrawn. The holding of the part must be done properly to prevent distortion of the metal. The mechanism used for this task is called the stripper. The hole in the stripper through which the punch passes should be designed with the proper amount of clearance to permit free movement of the punch. In some cases, slender punches may be guided by bushings installed in the stripper plate.

Actually, a stripper may be a component of either the punch assembly or the die assembly. If it is a component of the punch, it is called a spring stripper, because the stripping pressure is supplied by springs that hold the stripper to the stock as the punch begins to ascend. As the punch moves up, the stripper is picked up by the punch after the part has been freed.

If the stripper is mounted on the die, it is called a solid stripper. The solid stripper is firmly mounted and does not move. It is generally used for large stampings or for stampings of heavy-gage material.

### Piercing Shear and Clearances

In piercing operations, one of the factors to consider is provision of safeguards against excessive tool breakage. In addition, the holes created must conform to certain quality

requirements with respect to size and edge conditions. Edges should generally be free from excessive burrs. The provision of proper clearances and shear can aid considerably in reducing tool breakage and providing desired quality.

**Shear.** In hole-cutting operations, the metal cut out is the scrap. Hence, any shear provided must be ground on the punch. The main purpose of shear is to reduce the load placed on the punches to accomplish the piercing.

Shear, to be of any advantage, should be ground on punches having diameters that are fairly large in relation to stock thickness. Shear on small punches may cause deflection of the punch and add to the likelihood of tool breakage. However, the benefits of shear may be provided where a number of small punches are being used by stepping the punches (Fig. 19). In this way, the pressure required to effect piercing is reduced by staggering the contact of the punches with the metal. The amount of punch stepping should be held to a minimum to avoid a jerky series of loads and releases as the punches progress through the metal. If the punches must enter the metal by 25% of stock thickness to effect shearing, each punch needs to be shorter than the next by no more than this amount.

**Clearances.** Tonnage requirements for piercing, and the quality of hole edges, are dependent, in part, on the provisions made for clearance between punch and die. The proper amount of clearance will result in a satisfactorily clean hole. Excessive clearance will result in rough, burred edges, distortion of material surrounding the cut, and pinched-off edge rather than a clean fracture. Insufficient clearance will result in unnecessarily high tonnage requirements because of the secondary and even tertiary shearing that takes place where insufficient clearance is provided. This greater force required under these conditions is apt to shorten tool life. In addition, particles of metal may be released during the secondary shearing. These particles may adhere to the punch surface and result in oversized or irregular holes. This adhering metal, called pickup, also increases tonnage requirements and may result in tool breakage due to deflection caused by a buildup of metal on one side of the punch. In addition to these undesirable effects, secondary or tertiary shearing leaves the internal surfaces of the hole ragged.

Proper clearances between punch and die are based on a percentage of stock thickness. This percentage is ground off the die hole, all around. The clearance varies with the type of material used. Generally, the harder the metal, the less the clearance. The range of clearances for most automotive stampings is considered to lie between 5 and 10% of metal thickness. The proper clearance is usually determined in die tryout.

### Special Factors in Piercing

To establish successful piercing operations, thought should be given to certain special factors.

**Proximity of Punches.** Where a number of holes are punched close together, certain provisions should be made to prevent excessive tool breakage. This breakage may result from the crowding of metal that takes place in piercing. For instance, a small punch adjacent to a large punch may be deflected and broken as the result of the large punch crowding the metal in the direction of the small punch. This problem may be overcome by grinding the smaller punch shorter by an amount equal to the distance the larger punch must travel to shear the stock. In this way, the metal is already crowded before the smaller punch makes contact. Also, the smaller punch retracts first and thus escapes any side pressure resulting from springback when the large punch is withdrawn.

**Sharpness of Tools.** The sharpness of cutting edges in piercing operations has an important bearing on the quality of work done and the pressure required to do the work. A sharp edge localizes the severest stresses and causes the fracture to occur sooner and with less load. Thus, maintenance of tool edges provides protection against punch breakage. It also helps to ensure clean fractures.

**Limitations of Piercing.** Theoretically, the size and number of holes that can be pierced, and the thickness of stock that can be used, are limited only by the size and strength of the press. However, for producing specific parts in conformance to specifications, certain practical limitations should be observed.

The number of holes that can be pierced in one die is limited by the space required for assembly of punches and die buttons. The size of the holes to be pierced is another determining factor in the number of these items that can be arranged in a single die setup. While it is usually economical to combine piercing operations in a single die, care should be taken to avoid excessive die-maintenance problems caused by a weakening of the die by inclusion of too many operations.

There is usually no difficulty in piercing any thickness of stock used in automotive stampings. However, in piercing heavier-gage stock, care should be taken to provide punches sturdy enough to withstand the stresses involved. Proper guiding of punches is necessary to avoid excessive tool breakage.

Fig. 19 Punches stepped to avoid breakage

Certain limitations should be observed in piercing close to the edges of stock or flanges. The general rule is to keep the outer edge of the hole at least two stock thicknesses from the edge of the material. With respect to flanges, at least three stock thicknesses should be allowed between the hole edge and the inside surface plane of the flange. The main purpose of this is to preserve adequate strength in the die button. The walls of the button must be thick enough to withstand the force exerted by the punch. If this thickness is reduced too much, in an effort to bring the die button hole close to the edge of the flange, repeated failure of the button may result. If a hole is pierced too close to a flange breakline prior to forming of the flange, undesirable distortion of the hole may take place during flanging. Where part design calls for holes in these limiting areas, a change in design may be necessary.

Most piercing is done with the punch traveling in a direction perpendicular to the horizontal plane of the stock. This provides the optimal conditions for punch strength and clean shearing. However, it is sometimes advantageous to pierce at some other angle (Fig. 20). Such a case may occur when piercing follows forming and the area to be pierced is at an angle to the horizontal. As the punch descends, it first contacts the work on one side of the point. This, of course, tends to deflect the punch, requiring careful guiding. The greater the workpiece angle from horizontal, the more difficult it is to pierce with vertical punch travel. Actually, piercing in such a situation is limited to a part angle of 30° or less. If piercing is attempted at a greater angle, exorbitant costs will be incurred due to punch breakage.

The proximity of holes to each other is another factor that puts a limitation on piercing. This limitation applies only to equipping the punch and die assemblies with standard punches and die buttons. Holes actually can be pierced very close to each other; they may even overlap. However, when such piercing is done, special punches, punch holders, and die buttons are required, because the sides of the punches and the die buttons must be ground down to bring the hole-producing elements close together. The use of special piercing units may be justified on the basis of savings resulting from combining of operations. However, a comparison of tooling

and operating costs for special units with costs of other methods should be undertaken to determine the best method.

### Cam Piercing

Piercing is a type of press operation that often can be successfully combined with other operations such as blanking, forming, and trimming. The economies that can be realized through combining of operations should always be considered when setting up a piercing operation. In addition, combining piercing with other operations is often a means of carrying out a greater amount of work with a limited number of presses.

In combining piercing operations, it is frequently unfeasible to pierce with a vertically held punch. This is true where the area to be pierced is in an angular position. In such a case, a cam-piercing mechanism may be used to bring the punch into right-angle contact with the part, the cam moving in from the side.

There are several types of cam mechanisms. The type selected for a particular application depends on such factors as space available for mounting the cam, pressure requirements for cam return, and the direction of piercing.

**Spring-Return Cam.** A spring-return cam (Fig. 21) consists of three main elements: the cam body, the driver, and the spring. The cam body carries the punch and is mounted on a base in such a way that the piercing punch may freely enter the die button, which is mounted in proper position on the die shoe. The driver is a wedge-shaped steel block mounted on the ram of the press. On descent of the ram, the wedge face acts on a similar surface of the cam body, causing the cam body to move in toward the die button. As this occurs, the cam spring is depressed. When the driver moves up, the spring expands to withdraw the cam body and its attached punch.

**Air-Cylinder-Return Cam.** The components and method of operation of an air-cylinder-return cam are very similar to those of a spring-return cam. The difference lies in the fact that an air cylinder is used instead of a spring to return the cam body to the open position on the upstroke of

the press. Air cylinders usually work more satisfactorily than springs as return mechanisms. In addition, the air cylinder is considered safer, because springs sometimes break and may scatter pieces of metal around the work area, endangering employees.

**Positive-Motion Cam.** Some cam operations are accomplished with the use of a positive-type driver. This driver consists of a mechanism that engages the cam body throughout the work stroke, pressing the cam body inward on the downward stroke and retracting it on the upward stroke. No springs or air cylinders are used. This type of mechanism is called a positive-motion cam (Fig. 22). The cam body may be located on either the punch or the die. If the cam is on the punch, the driver is fastened to the die, and vice versa.

**Internal Cams.** In some cases, the location of the burr that is created on a part in a piercing operation is highly important. Sometimes, because of limited assembly clearances, a burr may not be tolerated on the interior surface of a part. The part may, however, be so positioned in the die where piercing is to be done that piercing in the normal way would induce burrs on the part interior. To avoid this, it may be necessary to pierce the part from the inside. This may be accomplished through the use of cams that work from inside the part when the part is in the die. These cams are linked to moving press mechanisms and carry the punch. The punch contacts the stock from the inside and forces a slug into a die button mounted outside the part on the punch, or perhaps on another cam mechanism.

### Piercing and Extruding

Quite often in press operations, a hole must be produced with an extruded collar all around it. This collar may be designed to strengthen the part or to serve as a locating device or as a bearing for a shaft. To provide such a collar, a special type of die arrangement is necessary. The type of arrangement used will depend on the direction of the extrusion and the gage of the stock.

Fig. 20 Piercing at an angle

Fig. 21 Piercing with a spring-return cam

Fig. 22 Piercing with a positive-motion cam

**Pierce and Extrude Up.** To accommodate other operations, the part may be positioned in a die in such a manner as to require an upward forming of the extrusion (Fig. 23). In such a case, the upper shoe is equipped with a punch and a spring pad to hold the workpiece and keep it from shifting. A spring pad is also fitted to the lower shoe. This spring pad acts as a holding device during extrusion and strips the part when forming is completed. The lower shoe also contains a specially designed die button. In operation, the punch descends and the upper spring pad grips the metal while the punch pierces through the stock into the die button. As the punch continues down, the pressure of the lower spring pad is overcome, and the pad moves downward. As the pad moves down, the free metal around the hole is extruded upward around the die button. The lower spring pad strips the part from the die button on the upstroke.

**Pierce and Extrude Down.** The position of the part in the die may require that the extrusion be formed downward (Fig. 24). In this type of operation, the piercing punch, is assembled in an extrusion punch, and both are mounted on the upper shoe, along with a spring pad. A lower spring pad is built around the die button, which is mounted on a plate that rides on an air cylinder or on springs. In operation, the upper pad grips the metal as the punch descends. The piercing punch pushes a slug out of the stock and continues down until the extrusion punch contacts the hole edges and wipes them down as the die button is pushed down. On the upstroke, the piercing and extrusion punches are withdrawn, and the die button rises to strip the extruded portion of the panel out of the die opening.

**Extruding Heavy-Gage Metal.** Heavy stampings are often designed with hole extrusions that can serve as sturdy housings for bushings or other shaft-bearing units. When the material is of very heavy gage, the hole should be drilled rather than pierced. This is necessary because in heavy stock, cracks and fractures occur in extrusions formed from the edges of pierced holes.

### Combined Operations

Piercing can be combined with practically any other type of stamping operation. In such com-

**Fig. 23** Pierce and extrude up

lined operations, however, it is necessary to provide careful guidance between the punch and die.

Piercing is often combined with blanking when the holes will not be deformed in later operations. Dies for blanking are usually well guided and provide suitable protection for piercing tools. The same is true of trimming operations.

Piercing may also be performed in conjunction with drawing, forming, and restriking operations if hole distortion does not result and if the press tools are properly guided.

### *Presses Employed in Piercing*

In nearly all cases, piercing is done on single-action presses. These presses may be of gap-frame or straight-side design. A triple-action press may also be used for piercing, the piercing being done with the third ram. In rare cases, a double-action press operation may incorporate a piercing punch that cuts through the metal just prior to bottoming to allow relief in an area of deep draw.

Presses selected for piercing should have adequate die area so that provision can be made to allow slugs to fall through the die base. Space for providing slug chutes under the die may be made through the use of risers.

Presses for piercing should also be in good mechanical condition. This will help to avoid tool breakage due to variations or shiftings in the press stroke resulting from worn press parts.

Hydraulic piercing mechanisms are sometimes used for operations in which only piercing is performed. Such mechanisms consist of hydraulic cylinders that are mounted on a fixture base and that carry the punches. The number of cylinders is dependent on the number of holes to be produced. Die buttons are mounted in proper locations on a fixture that positions the part for the operation. In operation, the part moves into the fixture, usually automatically, and the cylinders are activated to effect piercing.

This type of mechanism is used in piercing the various holes in assembled automobile frames. By piercing all of these holes in one fixture, at one time, the physical relationship of the holes

**Fig. 24** Pierce and extrude down

may be held to closer tolerances. Performing the same type of operation in a press would be much more costly because of the greater expense of the required equipment.

Hydraulic piercing units are also used for piercing various hole patterns in fenders to accommodate various trim designs. They are also used in piercing rivet holes and air valve holes in automobile wheels.

These mechanisms provide a means of piercing at low cost, are adaptable to quick changeovers, and are versatile in application. However, the use of hydraulic cylinders and hydraulic lines creates maintenance problems that are both costly and troublesome.

## Fine-Edge Blanking and Piercing

Fine edge blanking is primarily used to obtain blank or hole edges comparable to machined edges. In fine edge blanking, there is no die break, and the entire wall surface of the cut is burnished. No further finishing or machining operations are necessary. Specially designed single-operation or compound blanking and piercing dies are generally used for the process. Applications of fine-edge blanking include production of components for instruments, watches, and office machines such as levers, gears, fingers, tooth segments, and similar parts (see the article "Fine-Edge Blanking" in this Volume). Fine-edge blanking is also being applied to a wide variety of materials, as well as to thicker stock, in the automotive, farm equipment, ordnance, machine tool, printing machine, household appliance, and textile machine industries. Gears, racks, sprockets, and other toothed forms are easily produced and are common applications.

Fine-edge blanking and piercing are actually more akin to cold extrusion than to a cutting operation. In fine-edge blanking, a V-shaped impingement ring (Fig. 25) is forced into the stock to lock it tightly against the die and force the work metal to flow toward the punch so that the part can be extruded out of the strip without fracture or die break. Die clearance is extremely

**Fig. 25** Typical tooling setup for fine-edge blanking of a simple shape

small and punch speed is much slower than in conventional blanking. Fine-edge piercing can be done either separately or at the same time as fine-edge blanking. In piercing small holes, an impingement ring may not be needed. Specially designed single-operation or compound blanking and piercing dies generally are used for the process.

**Process Capabilities.** Holes with diameters as small as 50% of stock thickness can be pierced in low-carbon steel. In high-carbon steel, the smallest hole diameter is about 75% of stock thickness. Holes can be spaced as close to each other, or to the edge of the blank, as 50 to 70% of stock thickness. Total tolerances obtainable are 0.013 mm (0.0005 in.) on hole diameter and for accuracy of blank outline; 0.025 mm (0.001 in.) on hole location with respect to a datum surface; and 0.025 mm (0.001 in.) on flatness.

No die break shows on the sheared surface of the hole. Blank edges may be rough for a few thousandths of an inch of thickness on the burr side of the part when the width of the part is about twice the stock thickness or less. Finish on the sheared edge is governed by the condition of the die edge and the land within the die. Parts fine-edge blanked from stainless steel will have a surface finish of 0.8  $\mu\text{m}$  (32  $\mu\text{in.}$ ) or better. Smooth edges also are produced on spheroidize-annealed steel parts. Burr formation increases rapidly during a run necessitating frequent grinding of the cutting elements.

Chamfers can be coined around holes and on edges. Forming near the cut edge, or forming offset parts with a bend angle of up to 30°, is possible under restricted conditions.

Metals up to 3.18 mm (0.125 in.) thick having a tensile strength of 585 to 795 MPa (85 to 115 ksi) are easily blanked. Parts up to 13 mm ( $\frac{1}{2}$  in.) thick can be blanked if press capacity is available. Material thicker than 3.18 mm (0.125 in.), especially steel having a carbon content of 0.25% or more, requires an impingement ring on the die so that the corners on the part will not break down. The edges of parts made of 1018 steel work harden as much as 7 to 12 points Rockwell C during blanking. In tests on 0.60% C spring steel with a hardness of 37 to 40 HRC, the surface finish on the sheared edges was 0.8  $\mu\text{m}$  (32  $\mu\text{in.}$ ) or better, but punch life was only 6000 pieces.

**Blank Design.** Limitations on blank size depend on thickness, tensile strength, hardness of work metal, and on available press capacity. For example, perimeters of approximately 635 mm (25 in.) can be blanked in 3.18 mm (0.125 in.) thick low-carbon steel (1008 or 1010). It is possible to blank smaller parts from low-carbon or medium-carbon steel that is about 12.7 mm ( $\frac{1}{2}$  in.) thick.

Sharp corner and fillet radii should be avoided when possible. A radius of 10 to 20% of stock thickness is preferred, particularly on parts over 3.18 mm (0.125 in.) thick or those made of alloy steel. External angles should be at least 90°. The radius should be increased on sharper corners or on hard materials.

Parts with tiny holes or narrow slots to be pierced, or with narrow teeth or projections to be blanked, may not be suited to fine-edge blanking. Hole diameter, slot width, or projection width should be at least 70% of metal thickness for reasonably efficient blanking, although features as small as 50% of stock thickness have been successfully formed.

These limitations have been exceeded. For instance, a 16 mm ( $\frac{5}{8}$  in.) diam hole was pierced in each end of a 1018 steel link 25 mm (1 in.) wide and 7.9 mm ( $\frac{5}{16}$  in.) thick. Because the part had a 13 mm ( $\frac{1}{2}$  in.) radius on each end, the wall thickness was 3.92 mm ( $\frac{3}{16}$  in.). The part was offset 2.54 mm (0.100 in.) in the same die. Holes 3.18 mm (0.125 in.) in diameter were pierced in a part made of 4 mm (0.156 in.) thick aluminum alloy 5052-H34, leaving a wall thickness of 1.0 mm (0.040 in.). A 1.6 mm (0.062 in.) diam hole was pierced in the same part.

The sheared faces of holes pierced during fine-edge blanking are usually vertical, smooth, and free from die break, provided the maximum hole dimensions are not more than a few times the stock thickness. As in conventional piercing, there is a slight radius around the punch side of the hole, but there are no torn edges on the die side of the blank. A rough-sheared surface on the blank may be caused by too great a punch to die clearance, or improper location and height of the impingement ring for the material being blanked. On parts blanked to a small width to thickness ratio, a small, rough surface may be noticeable but may not be detrimental.

**Presses.** Triple-action hydraulic presses or combination hydraulic and mechanical presses are used for fine-edge blanking. The action is similar to that of a double-action press working against a die cushion. An outer slide holds the stock firmly against the die ring and forces the impingement ring into the metal surrounding the outline of the part. The stock is stripped from the punch during the upstroke of the inner and outer slides. An inner slide carries the blanking punch. A lower slide furnishes the counter action to hold the blank flat and securely against the punch. This slide also ejects the blank.

The stripping and ejection actions are delayed until after the die has opened to at least twice the stock thickness to prevent the blank from being forced into the strip, or slugs from being forced into the blank. Because loads are high and clearance between punch and die is extremely small, the clearance between the gibs and press slides must be so close that they are separated only by an oil film.

*Force requirements for fine-edge blanking presses* are influenced not only by the work metal and the part dimensions, but also by the special design of the dies and pressure pads used for fine-edge blanking (Fig. 26). Depending on part size and shape, an 890 kN (100 tonf) press can blank stock up to 8 mm (0.315 in.) thick; a 2.2 MN (250 tonf) press can blank stock up to 11.9 mm (0.470 in.) thick; and a 3.6 MN

(400 tonf) press can blank stock up to 12.7 mm (0.500 in.) thick.

**Tools.** The design of tools for fine-edge blanking is based on the shape of the part, the method of making the die, the required load, and the extremely small punch to die clearance. The considerable loading and required accuracy dictate that the press tools be sturdy and well supported to prevent deflection. The small clearance presupposes precise alignment of the punch and die.

A basic tool consists of three functional components, the die, the punch, and back-pressure components. To produce high-quality blanks, the punch to die clearance must be uniform along the entire profile and must be suitable for the thickness and strength of the work metal. Clearance varies between 0.005 and 0.01 mm (0.0002 and 0.0004 in.).

The components of a typical tooling setup for fine-edge blanking of a part of simple shape are shown in Fig. 25. The profile part of the blanking punch is guided by the pressure pad. A round punch is prevented from rotating by a key fastened to the upper die shoe. The hardened pressure pad is centered by a slightly conical seat in the upper die shoe; this pad contains the V-shaped impingement ring.

Some diemakers put a small radius on the cutting edge of the die. This causes a slight bell-mouth condition that produces a burnishing action as the blank is pushed into the die, improving the edge finish. If holes are to be pierced in the part, the blanking punch will contain the piercing die. The slug is ejected by ejector pins or through holes in the punch.

The die is centered in the lower die shoe by a slightly conical seat, as is the upper pressure pad. Both the die and the upper pressure pad are preloaded to minimize movement caused by compression. The pressure and ejector pad is guided by the die profile and is supported by pressure pins and the lower slide. The backup block for the piercing punch also guides the

**Fig. 26** Force required for embedding impingement rings of various heights into several different work metals. A, stainless steel; B, prehardened alloy steel, C, mild steel, half-hard brass, hard copper, 6xxx aluminum alloys in the H temper; D, soft copper; series 6000 aluminum alloys, half hard; E, commercially pure aluminum, H temper

pressure pins. The die components are mounted in a precision die set with precision guide pins and bushings. Some designers prefer pressing the guide pins into the upper shoe.

**Tool Materials.** Because of the high loads, close tolerances, and small clearances involved in fine-edge blanking, the die elements are made of high-carbon, high-chromium tool steels, such as AISI D2 or D3, or of A2 tool steel heat treated to about 62 HRC. Punch and die life vary with

tool material and hardness, punch-to-die clearance, type of work metal, and workpiece dimensional and surface finish requirements. For most work metals under the usual operating conditions, punch life for fine-edge blanking of 3.2 mm ( $1/8$  in.) thick stock is 10,000 to 15,000 blanks between regrinds—assuming that the blanks are of simple shape and that punch wear is such that only 0.05 to 0.13 mm (0.002 to 0.005 in.) of metal must be removed to restore

the punch to its original condition. For more information on tool materials and coatings, see the article “Fine-Edge Blanking” in this Volume.

# Blanking of Low-Carbon Steel

BLANKING is the process that uses a die and press to cut or shear a piece of metal from flat or preformed stock. The resulting blank is a piece of metal designed to have a predetermined contour for subsequent forming operations. The blank ordinarily serves as a starting workpiece for forming; less often, it is a desired end product. Making blanks without using a die is referred to as shearing, as discussed in the article “Shearing of Sheet, Strip, and Plate” in this Volume.

The prime objective in planning a blanking-die operation is to design a blank with enough metal to shape the part and, at the same time, prevent excessive scrap loss due to trimming. The types of blanks used in sheet-forming operations fall into four convenient classifications:

- Rectangular blanks
- Rough blanks
- Partially developed blanks
- Fully developed blanks

These types of blanks are described in more detail in the section “Blanking Operations” in the preceding article “Blanking and Piercing” in this Volume. This classification of blanks has permitted the application of some general rules to follow in setting up the blanking operation for a part.

This article discusses the production of blanks from low-carbon steel (such as 1008 and 1010) sheet and strip in dies in a mechanical or hydraulic press. As a point of comparison with higher-strength steel, such as high-carbon steel, the most important difference between the blanking and piercing of high-carbon and of low-carbon steel is that greater clearance between punch and die is required for high-carbon steels. Table 1 gives clearances needed for producing different edge types (Fig. 1) for blanking and piercing high-carbon and low-carbon steels. As shown in Table 1 and in the accompanying Fig. 1, at equal clearance, rollover depth will be smaller and burnish depth greater for high-carbon than for low-carbon steel. For example, 12% clearance per side will produce a type 4 edge on high-carbon steel, and a type 2 edge on low-carbon steel. More information on the forming operations for high-carbon steels and high-strength sheet steels is in the respective articles “Forming of Carbon Steels” and “Forming of Advanced High-Strength Steels” in this Volume.

## Methods of Blanking in Presses

Cutting operations that are done by dies in presses to produce blanks include cutoff, parting, blanking, notching, and lancing. The first three of these operations can produce a complete blank in a single press stroke. In progressive dies, two or more of these five operations are done in sequence to develop the complete outline of the blank and to separate it from the sheet, strip, or coil stock.

Trimming is defined as the cutting off of excess material from the periphery of a workpiece. It is usually done in dies and is similar to blanking. It is often the final operation on a formed or drawn part. The quality of blanked edges also can be improved by shaving, as discussed later in this article. Fine-edge blanking is treated in the article “Fine-Edge Blanking” in this Volume.

The applications of these methods are described in examples throughout this article. Other examples of these methods of producing blanks are provided in the articles “Piercing of Low-Carbon Steel,” “Blanking and Piercing of Electrical Steel Sheet,” “Forming of Carbon Steels,” and “Deep Drawing” in this Volume.

**Cutoff.** This operation consists of cutting along a line to produce blanks without generating any scrap in the cutting operation, most of the part outline having been developed by notching or lancing in preceding stations. The cutoff line

can take almost any shape—straight, broken, or curved. After being cut off, the blanks fall onto a conveyor or into a chute or container.

A cutoff die can be used to cut the entire outline of blanks whose shape permits nesting in a layout that uses all of the material (except possibly at the ends of the strip), as shown in Fig. 2. Alternating positions can sometimes be used in nesting (middle, Fig. 2) to avoid producing scrap except at strip ends. Cutoff is also used to cut blanks from strip that has already been notched to separate the blanks along part of their periphery, as described in the following example.

**Example 1: Use of Cutoff to Separate Blanks Partly Outlined by Notching.** Figure 3 shows the layout for the cutoff of blanks for automobile body-bolt brackets. The brackets were completed by piercing and forming.

The coiled strip of galvanized hot rolled 1006 steel was 1.90 mm (0.075 in.) thick by 495 mm (19.5 in.) wide. This was wide enough for two blanks, as shown in Fig. 3. The blanks were alternated in the layout to facilitate trimming and piercing.

The strip was notched and seminotched in the first stations of a progressive die (making a small amount of scrap). In the following stations, straight cutoff punches made four blanks at each stroke without producing any additional scrap.

The work was done in a 3.6 MN (400 tonf) single-action mechanical press with an air cushion. The press was equipped with a double

**Table 1 Punch-to-die clearances for piercing or blanking various metals to produce the five types of edges shown in Fig. 1**

For clearances that produce type 1, 2, and 3 edges, it is ordinarily necessary to use ejector punches or other devices to prevent the slug from adhering to the punch.

Work metal	Clearance per side, % of stock thickness				
	Type 1(a)	Type 2	Type 3	Type 4	Type 5
Low-carbon steel	21	11.5–12.5	8–10	5–7	1–2
High-carbon steel	25	17–19	14–16	11–13	2.5–5
Stainless steel	23	12.5–13.5	9–11	3–5	1–2
Aluminum alloys					
Up to 230 MPa (33 ksi) tensile strength	17	8–10	6–8	2–4	0.5–1
Over 230 MPa (33 ksi) tensile strength	20	12.5–14	9–10	5–6	0.5–1
Brass, annealed	21	8–10	6–8	2–3	0.5–1
Brass, half hard	24	9–11	6–8	3–5	0.5–1.5
Phosphor bronze	25	12.5–13.5	10–12	3.5–5	1.5–2.5
Copper, annealed	25	8–9	5–7	2–4	0.5–1
Copper, half hard	25	9–11	6–8	3–5	1–2
Lead	22	8–10	6.5–7.5	4–6	1.5–2.5
Magnesium alloys	16	5–7	3.5–4.5	1.5–2.5	0.5–1

(a) Maximum. Source: Ref 1

roll feed and made 50 strokes (200 blanks) per minute.

**Advantages** of cutoff in making blanks include:

- The die has few components and is relatively inexpensive.
- Waste of material in blanking is minimized or eliminated.
- The die can be resharpened easily, and maintenance costs are low.

**Disadvantages** of cutoff include:

- It can be used only to make blanks that nest in the layout without waste.
- Cutting of one edge causes one-way deflection and stress.
- Accuracy may be affected adversely by the method of feeding.

**Parting** (Fig. 4) is the separation of blanks by cutting away a strip of material between them. Like cutoff, it can be done after most of the part outline has been developed by notching or lancing. It is used to make blanks that do not have mating adjacent surfaces for cutoff (Fig. 4) or to make blanks that must be spaced for ease of handling in order to avoid distortion or to allow room for sturdy tools. Some scrap is produced in making blanks by parting; therefore, this method is less efficient than cutoff in terms of material use.

**Blanking** (also called punching) is the cutting of the complete outline of a workpiece in a single press stroke. Because a scrap skeleton is usually produced, blanking involves some material waste. However, blanking is usually the fastest and most economical way to make flat parts, particularly in large quantities.

The skeleton left by blanking sometimes has only scrap-metal value, but many shops have organized programs to maximize the use of cutouts and sizable scrap skeletons in making other production parts. Material waste is completely avoided by using the scrap skeleton that remains from certain blanking operations to provide perforated stock for such items as air filters for forced-air furnaces.

**Piercing** (with a flat-end punch), also called punching or perforating, is similar to blanking except that the punched-out (blanked) slug is the waste and the surrounding metal is the workpiece. Piercing is discussed in the article "Piercing of Low-Carbon Steel" in this Volume.

**Notching** is an operation in which the individual punch removes a piece of metal from the edge of the blank or strip (Fig. 5).

(a) Rollover plus burnish approximately equals punch penetration before fracture. (b) Burnish on edge of slug or blank may be small and irregular or even absent. (c) With spotty secondary shear. (d) In two separate portions, alternating with fracture. (e) With rough surface. (f) In two separate portions, alternating with burnish. (g) Amount of compressive burr depends on die sharpness.

**Fig. 1** Effect of punch-to-die clearance per side (as a percentage of stock thickness, *t*) on characteristics of edges of holes and slugs (or blanks) produced by piercing or blanking low-carbon steel sheet or strip at a maximum hardness of 75 HRB. Table 1 lists clearances for producing the five types of edges in various metals. See text for additional discussion and for applicability of the five types of edges.

**Fig. 2** Nested layouts for making blanks by cutoff

**Fig. 3** Layout for the cutoff of four blanks at each press stroke from notched and seminotched strip. Dimensions given in inches

**Fig. 4** Use of a parting punch to make blanks not having mating adjacent surfaces

Notching is done for such reasons as the following:

- To free some metal for drawing (Fig. 5a) and for forming (Fig. 5b) while the workpiece remains attached to the strip
- To remove excess metal before forming (Fig. 5c)
- To cut part of the outline of a blank that would be difficult to cut otherwise (Fig. 3 and 29)

The piercing of holes of any shape in a strip to free metal for subsequent forming or to produce surfaces that later coincide with the outline of a blanked part is sometimes called **seminotching**. The pierced area may outline a portion of one part or of two or more adjacent parts in a strip. Figure 3 illustrates a progressive-die layout incorporating seminotching.

**Lancing** is a press operation in which a single-line cut or slit is made part way across the strip stock without removing any metal. Lancing is usually done to free metal for forming (Fig. 6). The cut does not have a closed contour and does not release a blank or a piece of scrap. In addition to its use in freeing metal for subsequent forming, lancing is also used to cut partial contours for blanked parts, particularly in progressive dies.

**Trimming** is an operation for removing excess metal (such as deformed and uneven metal on drawn or formed parts) and metal that was used in a previous operation (such as a blankholding flange for a draw operation). Trimming is done in several ways, depending on the shape of the workpiece, the accuracy required, and the production quantity.

Figure 7 illustrates the tooling for trimming a horizontal flange on a drawn shell in a separate operation. The drawn shell is set on a locating plug for trimming. After scrap from a sufficient number of trimmed shells has accumulated, the

piece of scrap at the bottom is severed at each stroke of the press by the scrap cutters shown in Fig. 7, and falls clear. Except that the die must be constructed to accept and locate the drawn shell, the operation is identical to the blanking of a flat workpiece and produces square edges of the same accuracy and quality. A drawn shell or formed part can be trimmed in a press without leaving a flange on the completed part by using one of three methods: pinch trim, shimmy trim, or trim and wipe-down.

**Pinch trimming**, shown as a separate operation in a push-through die in Fig. 8, is done only on a part that has at least a narrow flange as-formed. The shell must be free from wrinkles at or near the trimming line. The trimmed edge is not square with the sidewall but has the general shape shown in the lower right corner of Fig. 8. The accuracy of height resulting from pinch trimming is affected by variations in wall thickness and flange radius. To ensure an even pinch-off and to avoid sharp or rough edges, clearance between punch and die must be held to a minimum, and the punch must be kept sharp.

Pinch trimming is also done without a blankholder or holddown, using a die otherwise similar to that shown in Fig. 8. The scrap rings climb the punch until they are severed by being compressed against a scrap cutter, after which they are spread apart and allowed to run out along a track for disposal. Pinch trimming without a blankholder is particularly well suited to the high-volume production of eyelets and other small parts.

Pinch trimming is primarily a mass-production method. The production rate is high because only one stroke of the press is required to

complete the trim. The method is often combined with drawing in a compound draw-and-trim die to reduce production costs further. The disadvantages of pinch trimming are excessive burrs, sharp cut edge, and high die maintenance.

**Shimmy Trimming.** In trimming with a shimmy die (also known as Brehm or model trimming), the drawn shell is held in a close-fitting die of the exact shell height and trimmed in segments by the successive horizontal oscillations of an internal cam-actuated punch toward the outside of the shell. The resulting trimmed edge is square and closely resembles the conventional blanked edge on a flat part. Shell height is more accurate than with pinch trimming. In addition to its application to shells that must have square, accurate edges, shimmy trimming is used on shells that have a wrinkled or otherwise nonuniform top edge as-drawn (cutoff is done below the defects) and on shells that cannot be produced economically with even the narrow flange needed for pinch trimming.

Tooling costs for shimmy trimming are much higher than those for pinch trimming. Shimmy trimming is also slower because it requires four or more oscillations of the punch in one press stroke and cannot be combined with other operations in a compound die. Shimmy dies are inexpensive to maintain because they remain in alignment and therefore are not likely to wear by shearing or chipping.

**Trim and Wipe-Down.** In this type of trimming, a flange is cut to width using a die such as that shown in Fig. 7 and then wiped or straightened into line with the sidewall of the

**Fig. 5** (a) Notched work illustrating the use of notching for freeing metal before drawing, (b) before forming, and (c) for removing excess metal before forming

**Fig. 6** Strip that was lanced to free metal for forming

**Fig. 7** Single-operation die for trimming a horizontal flange on a drawn shell

**Fig. 8** Pinch trimming a drawn shell in a push-through die

shell or formed part. Because of narrow flange width, trimming and wiping down may be two operations.

The edge is square with the sidewall, but the shell height may be slightly irregular because of the forming characteristics of the metal. In addition, a ring may be visible at the original location of the flange radius.

Trimming, other than shimmy trimming, is frequently combined with one or more other operations in a compound die. Trim stock is often left on a drawn or formed workpiece so that it can be trimmed to size in a second operation. This is done to obtain the most accurate relationship of some other feature, such as a pierced hole, to the trimmed outline of the workpiece.

## Characteristics of Blanked Edges

The sheared edges of a blank produced in a conventional die are not smooth and vertical for the entire thickness of the part but exhibit the characteristics represented on an exaggerated scale in Fig. 9. The blank is shown in the position in which it would be cut from the work metal by the downward motion of the punch. A portion of the stock remaining after removal of the blank is shown at the top of the illustration.

Rollover on the lower edges of the blank develops by plastic deformation of the work metal as it is forced into the die by the punch. Compression of the metal above the rollover zone against the walls of the die opening burinishes a portion of the edge of the blank, as shown in Fig. 9. As the punch completes its stroke, the remaining portion of the blank edge is broken away or fractured (resulting in die break), and a tensile burr is formed along the top of the blank edge.

The angle of the fractured portion of the edge is identified in Fig. 9 as the breakout angle. The breakout dimension of the blank and the burnish dimension of the hole in the scrap skeleton are approximately equal to the corresponding punch

dimension, and the burnish dimension of the blank is very close to the corresponding die dimension. Therefore, the punch determines the hole size, and the die governs the blank size.

Penetration depth, or the amount of penetration of the punch into the work metal before fracture occurs, is shown on the edge of the remaining stock or scrap skeleton in Fig. 9. This depth is approximately equal to the sum of the rollover depth and the burnish depth on the blank, except when low die clearance produces secondary burnish. It is usually expressed as a percentage of the work metal thickness.

The percentage of penetration (before fracture) depends on the properties of the work metal, as shown in Table 2, which gives approximate values for various steels and non-ferrous metals under typical blanking conditions. The percentage of penetration affects energy consumption and cutting force in blanking, as described in the section "Calculation of Force Requirements" in this article.

## Die Clearance

The terms *clearance*, *die clearance*, and *punch-to-die clearance* are used synonymously to refer to the space between punch and die. Clearance is important for the reliable operation of the blanking equipment, the quality and type of cut edges, and the life of the punch and die. In general, the effects of clearance on these factors in blanking are the same as in piercing and are discussed in the article "Piercing of Low-Carbon Steel" in this Volume. The same article also describes the edge characteristics of slugs produced in piercing holes (see Fig. 2 of that article). The data in that illustration can serve as a guide for selecting clearances for blanking. All clearance values given in this article are per side, except where indicated.

Optimal blanking clearance may sometimes be less than optimal piercing clearance. This is partly because the blanked edge is generally

close to the stock edge, and material expansion is therefore less restricted. A piercing tool must move a great deal of material away from its cutting edge, and for longest life, the clearance should be selected to eliminate as much compressive loading on the work metal as possible.

A part blanked using clearance much greater than normal may exhibit double shear, which is ordinarily evident only with extremely small clearance (see edge types 4 and 5 in Fig. 2 in the article "Piercing of Low-Carbon Steel" in this Volume). In addition, a part blanked using large clearances will be smaller than the die opening (except for a deeply dished blank), and it is difficult to correct the tooling to compensate for this. In some applications, retaining the blank becomes almost as great a problem as expelling the slugs into a die cavity after piercing, because of the increased clearance.

**Relief** in a blanking die (Fig. 10) is the taper provided so that the severed blank can fall free. The relief angle may range from  $1/2$  to  $2^\circ$  from the vertical wall of the die opening. Relief in a die is sometimes called draft or angular clearance. In some dies, the relief may start at the top of the die surface and have a taper of only 0.002 in./in. (0.002 mm/mm) per side. In other dies, there is a straight, vertical wear land between the top of the die and the relief.

## Calculation of Force Requirements

Calculation of the forces and the work involved in blanking gives average figures that are applicable only when the correct shear strength for the material is used and when the die is sharp and the punch is in good condition, has correct clearance, and is functioning properly. The total load on the press, or the press capacity required to do a particular job, is the sum of the cutting force and other forces acting at the same time, such as the blankholding force exerted by a die cushion.

**Cutting Force: Square-End Punches and Dies.** When punch and die surfaces are flat and at right angles to the motion of the punch, the cutting force can be found by multiplying the area of the cut section by the shear strength of the work material:

$$L = S_s t l \quad (\text{Eq } 1)$$

where  $L$  is the load on the press (in pounds) (cutting force),  $S_s$  is the shear strength of the stock (in pounds per square inch),  $t$  is the

**Fig. 9** Characteristics of the sheared edges of a blank. Curvature and angles are exaggerated for emphasis.

stock thickness (in inches), and  $l$  is the length or perimeter of the cut (in inches). The shear strengths of various steels and nonferrous metals are given in Table 3.

**Cutting Force: Dies with Shear.** For cutting large blanks, shear can be applied to the face of the die by grinding it at an angle to the motion of the punch (Fig. 11), but shear is not used in cutting small blanks. Shear reduces shock in the press, as well as blanking noise and blanking force, but the same amount of work is done as with a flat die surface.

The most common type of shear used on the die is convex (Fig. 11a). The apex of the die face is slightly rounded to avoid initiating a crack in the work metal. Concave shear (Fig. 11b) is somewhat more difficult to grind on the die but holds the work metal more securely during blanking. A radius approximately equal to that of the grinding wheel is produced where the ground surfaces meet.

A third type of shear, sometimes used on a die for a large blank, consists of a wavy or scalloped surface around the die opening. This technique uses several convex and concave shear surfaces around the die opening. The punch load is distributed over the entire die surface, thus minimizing punch shift.

The amount of shear in a die can be less than or greater than stock thickness. Shear that is equal in depth or greater than the stock thickness is called full shear.

The cutting force for a die with shear can be calculated after first finding the work done (energy used) in blanking. The work done in blanking equals the force required in blanking (load on the press) multiplied by the distance that the force acted:

$$W = Ls \quad (\text{Eq 2})$$

where  $W$  is the work done in blanking (in inch-pounds),  $L$  is the load (in pounds), and  $s$  is the distance the load acts (thickness multiplied by percentage of penetration before fracture) (in inches). To obtain accurate work values,

the percentage penetration must be known accurately.

Cutting or blanking force is reduced by the use of angular shear in the die; the amount of reduction in force depends on the depth of the angular shear. The reduced average cutting force on the press is:

$$L_{sh} = \frac{W}{s + s_1} \quad (\text{Eq 3})$$

where  $L_{sh}$  is the average cutting force (in pounds), with angular shear,  $W$  is the work done in blanking (in inch-pounds),  $s$  is the distance (in inches) that the load acts (thickness multiplied by percentage of penetration before fracture), and  $s_1$  is the depth of angular shear (in inches).

In simplified practice, some plants ignore partial shear in calculating cutting force for blanking. When full shear is used, force is calculated as without shear and then reduced by 30%.

**Stripping force** is the force needed (when drop-through is not used) to free the blank from the die or the strip from the punch when they stick or jam because of springback. Stripping force can be calculated using:

$$L_{st} = kA \quad (\text{Eq 4})$$

where  $L_{st}$  is the stripping force (in pounds),  $k$  is a stripping constant (in pounds per square inch), and  $A$  is the area of the cut surface (in square inches) (stock thickness  $t$  multiplied by length or perimeter of cut  $l$ ). Approximate values for the constant  $k$  (as determined by experiment for low-carbon steel) are:

- 1500 for sheet metal thinner than 1.57 mm (0.062 in.) when the cut is near an edge or near a preceding cut
- 2100 for other cuts in sheet thinner than 1.57 mm (0.062 in.)
- 3000 for sheet more than 1.57 mm (0.062 in.) thick

## Factors That Affect Processing

Factors that affect the processing of blanks include:

- Size and shape of the blank
- Material for blanking

**Fig. 11** Convex shear and concave shear on blanking dies. Angle and depth of shear are exaggerated for emphasis. Normally, depth of shear does not greatly exceed stock thickness.

- Form in which the material is supplied
- Thickness of the blank
- Production quantity and schedule
- Quality specifications
- Availability of equipment and tools
- Number and type of subsequent operations required for completing the work

The size and shape of the blank affect the form and handling of the material blanked, the blanking method, and the handling of the completed blank. The thickness of the blank affects the press load required (see the section "Calculation of Force Requirements" in this article), the selection of equipment, and the choice of blanking and handling methods (see the section "Effect of Work Metal Thickness" in this article).

Production quantity and schedule determine the choice of equipment. A total production of fewer than 10,000 pieces is considered a short run; 10,000 to 100,000 pieces, a medium run; and more than 100,000 pieces, a long run.

Quality specifications and tolerances for thickness, camber, width, length, flatness, and finish affect the handling of the material. The availability of single-, double-, or triple-action presses (rated at various force capacities, sizes, speeds, lengths of stroke, strokes per minute, and shut heights) affects the selection of the processing method. The availability and capacity of auxiliary press equipment can have an effect on the selection of a tooling system and on whether a part can be made in-plant.

Operations that follow blanking also affect the choice of equipment, the processing method, and the handling procedures. Such subsequent operations may include piercing, bending, forming, deep drawing, machining, grinding, or finishing. Only rarely is the blank a final product.

## Selection of Work Metal Form

Work metal for blanking in presses is usually in the form of flat sheets, strip, or coil stock. Less frequently, steel plate is blanked in presses (see the section "Effect of Work Metal Thickness" in this article). In some applications, the metal is preformed before blanking.

Special preparation of the work metal is usually not required for the blanking operation itself. However, annealing, leveling, or cleaning is often needed because of subsequent forming operations on the blank, as discussed in the article "Forming of Carbon Steels" in this Volume.

**Sheet or Strip.** Flat sheet is usually the work metal for large blanks, such as automobile roofs. Square-sheared sheet can be used as a blank, or it can be blanked in a die. Small quantities of blanks, regardless of size, are usually made from straight lengths of sheet or strip.

**Coil stock** is used for mass production, whenever possible. In continuous production, the use of coil stock can save as much as one-third of the time needed for producing an equal quantity

**Table 3** Shear strengths of various steels and nonferrous metals at room temperature

Metal	Shear strength	
	MPa	ksi
<b>Steels</b>

from flat stock. In addition, there are fewer scrap ends when coil stock is used.

Sheet metal is the least expensive when it is supplied in large coils from the mill. For most applications, the coil must be slit to the proper width for blanking, and some edge material must be trimmed off. Parts can sometimes be made most economically in a progressive die by using coil stock that is the width of the developed blank.

## Blank Layout

In the medium and high production of medium-sized blanks, the cost of material is 50 to 75% of the total cost of the blank; for large blanks, it may be more than 95% of the total cost of the blank. Substantial savings in net material cost can often be achieved by coordinating blank layout with the selection of stock form and width to minimize the amount of scrap produced.

Several trial layouts may be needed to find the width of stock and the layout that use the material most efficiently while taking into account the possible effects of orientation of parts on subsequent operations. The layout must include the minimum workable scrap allowance between blanks, providing just enough material to support or hold down the strip during blanking. Scrap allowances, based on the use of well-maintained equipment and good shop practice, are given in Table 4.

The percentage of scrap in a strip layout can be calculated as:

$$100 \left( 1 - \frac{A_B}{A_S} \right) \quad (\text{Eq } 5)$$

where  $A_B$  is the area of blanks produced in one press stroke, and  $A_S$  is the area of strip consumed by one press stroke, or strip width times feed length.

**Round blanks** can be staggered in rows, at the same spacing as for hexagons (Fig. 12), for the most efficient blanking from a long strip. With such a layout, 20 to 40% more blanks can be made from a given amount of material than by blanking each circle from a separate square. With the layout shown in Fig. 12, each press stroke (after the third stroke) produces four blanks—spaced to provide enough room for mounting the punches and dies.

The percentage of scrap loss for the layout of Fig. 12 can be calculated using Eq 5 and the following:

$$\begin{aligned} A_B &= \frac{n\pi D^2}{4} \\ A_S &= wl \\ l &= D + s \\ w &= (d + 2s) + (n - 1)(D + s) \cos \alpha \quad (\text{Eq } 6) \end{aligned}$$

where  $n$  is the number of rows of blanks across the strip width,  $D$  is the blank diameter (in inches),  $l$  is the feed length (one blank made in each row per press stroke) (in inches),  $w$  is the strip width (in inches),  $s$  is the scrap allowance from the edge of the strip to the blank and between blanks (in inches), and  $\alpha$  is the angular displacement between blanks (in degrees). The area of the holes pierced in a blank is not considered in these calculations, because it does not affect the efficiency of the layout.

**Rectangular blanks** can generally be laid out more easily than other shapes.

**Odd-shaped blanks** are generally more difficult to lay out for the greatest economy.

**Nesting**, or the interlocking of blanks in the layout to save material, should be done wherever the shape of the blank permits. Nesting is possible with many irregular blanks.

Figure 13 shows a layout in which irregular blanks are nested so that an appreciable amount of material is saved. A double die can be used with such a layout, blanking two pieces per

stroke. A single die can be used for short runs; the strip is turned around after the first pass and fed through the die again.

Another way of nesting blanks is a layout such as that illustrated in Fig. 14. With this layout, three punches cut four pieces per stroke (after the third press stroke) in a shearing action that produces no scrap except at the ends of the strip. Other strip layouts in which the blanks have been nested are shown in the article "Forming of Carbon Steels" in this Volume.

**Use of Full Stock Width.** Blanks that have two parallel sides can sometimes be made most economically in a layout that uses the full width of the stock. The remaining outline of the blank is produced by shearing, lancing, notching, parting, or a combination of these.

**Effect of Rolling Direction.** For blanks that must later be bent or formed, consideration must be given in layout to the orientation of the blanks with respect to the direction of rolling (grain direction). Ideally, blanks should be laid out so that severe bends are made with the bend axis at

right angles to the direction of rolling or, if this is not practical, with the bend axis at an angle to the direction of rolling. Stretching should be in the direction of rolling, whenever possible. Examples and illustrations of blank layouts are provided in the article "Forming of Carbon Steels" in this Volume.

## Welded Blanks

Tailor welded blanks are widely used in automobile manufacturing (see the article "Forming of Steel Tailor-Welded Blanks" in this Volume). Welded blanks also are used when they have advantages over one-piece blanks, as in the following situations:

- The welded blank may cost less than an equivalent one-piece blank if scrap or other low-cost metal can be used to make the welded blank or if tooling and production for the one-piece blank cost more than for the welded blank.
- Stock for a welded blank may be more readily available than stock for an equivalent one-piece blank.
- The blank may have a shape that would waste more material if it were made in one piece instead of being welded. Material can sometimes be saved by welding projecting portions, such as tabs and ears, to simpler shapes.
- The welded blank, when used in subsequent forming operations, may reduce the cost of tooling. Flat or simple shapes are welded in a layout designed to avoid the presence of seams in certain portions of the blank and to permit automatic welding, if possible.

**Large blanks** that would cost extra because of width or for other reasons if they were made in one piece can sometimes be made at less cost by welding.

**Difficult shapes** that would waste a considerable amount of material if they were made in one piece can sometimes be made by welding two or more simple blanks together. In the application described in the following example, two developed blanks were welded and then formed into a bent channel.

**Example 2: Use of Two Gas Metal Arc Welded Blanks to Form an Automobile-Frame Rail.** Figure 15 shows a side rail for an

**Fig. 14** Layout for the scrapless blanking of four blanks per press stroke, using three punches. The three shaded shapes for each press stroke denote the blanks produced directly by the three punches. The unshaded shape for each press stroke denotes a blank produced by the action of adjacent punches. Numbers show order of press strokes

automobile frame that was formed from 5.05 mm (0.199 in.) thick hot rolled commercial-quality 1008 steel. The blank for this rail had a shape that could be made in one piece only with excessive waste of metal in scrap. The two pieces used were blanked from nested layouts with little scrap waste.

Blanking was done in a die that made both pieces in a single press stroke. The two portions were butted and joined by high-speed automatic gas metal arc welding and then formed. Tolerance on all dimensions shown in Fig. 15 was  $\pm 0.51$  mm ( $\pm 0.020$  in.).

The savings in metal exceeded the cost of welding, but if production needs had been fewer than 10,000 pieces, the savings in metal would not have paid for the welding and the blanking dies. The production quantity was 300,000 rails made in lot sizes of 20,000 pieces.

**Open Shapes.** A blank with a large cutout can sometimes be made at less cost than a one-piece blank by welding simpler pieces together.

**Waste metal** can sometimes be joined by welding to make a blank that costs less than a one-piece blank.

**Welding methods** used in making blanks include resistance welding methods (lap-seam, spot, foil butt-seam, mash-seam, flash, and high-frequency butt) and fusion welding.

**Lap-seam welding** (wheel electrodes) is a frequently used method. Tooling is simple if the components are joined first by tack welding. The disadvantages of lap-seam welding are loose edges, and joints that are double the thickness of the work metal.

**Spot welding** is fast and needs only simple, inexpensive tooling. The disadvantages of spot welding are loose edges, and joints that are not tight and are not as strong as those made by other methods.

**Foil butt-seam welding** is a fast method that makes smooth, tight joints with no loose edges. Its disadvantages include the cost of adding foil to one or both sides of the seam and the need to use starting tabs to make strong joints.

**Mash-seam welding** makes smooth joints that often need no grinding and tight joints that have no loose edges. Disadvantages include the short

life of electrodes and the high cost of tooling resulting from the difficulty in maintaining the small overlap.

**Flash welding** uses simple tooling; the joints are tight and free from loose edges. However, the length of joint that can be produced by flash welding is limited, and the joints are rough and therefore must be ground before the weldment can be worked in a die.

**High-frequency butt welding** is fast and can be used to join two dissimilar metals. Electrode life is good. However, costly equipment is required, and the technique is generally suitable only for mass production.

**Fusion welding** methods include gas metal arc welding and gas tungsten arc welding.

## Presses

Most blanking is done in single-action mechanical presses. Some dies can be used only with a particular type of press; the die is usually made to suit a specific press. The force capacity rating must be adequate for the work and must be well above the calculated cutting force (see the section "Calculation of Force Requirements" in this article). Press capacities are given in kilonewtons (tons of force) at a certain distance above the bottom of the stroke. This distance must suit the die and the operation. Most blanking is done near the bottom of the stroke where the available force is greatest. In compound dies, blanking may be done near mid-stroke, where the available force is much lower than that at the bottom.

Size of bed, shut height, stroke length, and speed must all be suitable for the die and the work. Some types of dies can be run at high speeds, and some need moderate or slow speeds, as discussed in the following section in this article.

## Construction and Use of Short-Run Dies

Small and medium quantities of blanks are often produced in punch presses by the use of inexpensive short-run dies. These include steel-rule dies, template dies (sometimes called plate dies or continental dies), and subpress dies. Although most applications of such dies are for production quantities of a few hundred to 10,000 pieces, suitably constructed dies of these types have been used for quantities of 100,000 pieces or more.

Short-run dies are used to a limited extent to blank initial quantities of parts that are to be mass produced. Because they can be made and put into operation more quickly than conventional dies, short-run dies make it possible to expedite the delivery of completed parts.

In addition, short-run dies are used to produce trial lots of parts that may be subject to extensive changes in design. If the trial lots show that die design changes are needed, the changes can be

**Fig. 15** Automobile-frame side rail that was formed from two blanks joined by gas metal arc welding. Dimensions given in inches

made at less cost before the conventional die is completed. After the conventional die has been set up, either the entire production can be transferred to it or both dies can be used.

For small quantities (<100 pieces), even the most inexpensive short-run blanking die may not be justified. Such small quantities of blanks are generally cut at less cost with standard tools, such as a nibbler, a squaring shear, or a rotary shear. Small quantities of blanks can also be made by contour band sawing, routing, gas cutting, filing, or machining.

**Steel-rule dies** are simple, inexpensive dies that are made by setting thin, bevel-edged strips of high-carbon tool steel on edge to outline the blank. The rule is set tightly into a slot in plain or impregnated plywood, and the plywood is backed by a steel subplate, as shown in Fig. 16. The die plate or template is attached directly to a steel subplate, and both upper and lower subplates are fastened to master die shoes, which are mounted in a conventional press.

Steel-rule dies are used for blanking, piercing, notching, and shallow forming. For work on flat blanks or on flat, sheared stock of low-carbon steel up to approximately 13 mm ( $1/2$  in.) thick, a steel-rule die can usually be made more rapidly and at less cost than any other kind of die. Blanks as large as 1.2 by 2.1 m (4 by 7 ft) have been made in steel-rule dies.

**Die.** The steel rule that is used as the die is made of high-carbon steel or of a tool steel such as W1 or W2, in spring temper and other hardnesses. It is available in stock lengths in several thicknesses, ranging from 0.36 to 4.32 mm (0.014 to 0.170 in.), and in widths of 31.8 mm (1.25 in.) and narrower. Printers' rules of thickness from 1 to 12 points (0.36 to 4.32 mm, or 0.014 to 0.170 in.) are sometimes used. The finished rule usually has a square back edge, and

a cutting edge that is ground to a  $45^\circ$  bevel or to a V-edge.

The back edge is fitted tightly into sawed slots in hard plywood, as shown in Fig. 16, so that it will cut the outline of the blank. The steel subplate is used to back up the steel rule and to support the plywood.

**Punch.** For blanking low-carbon steel, a die plate (high-carbon or tool steel template) of the same shape as the required blank is used as the punch, opposing the steel rule. Other punch elements and die parts are added as needed to the die for piercing holes and slots at the same time that the blanking is done. Solid steel blocks, instead of a steel rule, can be used in the die to cut sharp corners and notches in the blank. For some work, including the cutting of paper and other soft materials, the punch can be a block of hard wood or a thick sheet of rubber or other soft material with a working surface that extends beyond the area enclosed by the steel rule.

**Stripper.** For cutting paper and leather, the steel-rule die is stripped by elastic material, such as sponge rubber, which is added to the die. In blanking low-carbon steel, blocks of tougher solid rubber can be used as strippers. Positive spring-loaded steel stripper plates are also used.

The accuracy of the blanks produced in steel-rule dies depends mainly on the skill of the diemaker and the care used in their construction. For noncritical parts blanked in steel-rule dies, the tolerance may be as large as  $\pm 0.8$  mm ( $\pm 1/32$  in.); for more critical parts, the work can be located accurately to maintain a tolerance of  $\pm 0.13$  mm ( $\pm 0.005$  in.). Closer tolerances on blanks can be obtained at increased cost by using rotary-head millers or jig boring machines in constructing the dies.

Because holes and slots made by steel-rule blanking are pierced with conventional punch

and die elements that are added to the steel-rule die, they can be produced to the same tolerances as in conventional blanking. Steel-rule dies commonly blank laminations with burrs only 0.05 mm (0.002 in.) high.

**Cost.** A steel-rule die made to blank low-to-moderate quantities of low-carbon steel generally costs approximately 20% as much as a conventional die made for the mass production of similar work. The following example describes the use of a steel-rule die for stopgap and trial production of an automobile part. A die change was made inexpensively; after it was proved successful in the steel-rule die, the same change was then included in the design of the conventional die for production use.

**Example 3: Use of a Steel-Rule Die for Temporary Production.** A steel-rule die was used to blank a part for an automobile frame in order to begin production without waiting until the conventional die could be delivered. It was expected that the steel-rule die would have to produce 325 blanks before production could be changed to the conventional die.

The die, shown in Fig. 17, was used in a 2.2 MN (250 tonf) straight-side press to blank annealed cold-rolled low-carbon steel, 3.96 mm (0.156 in.) thick by 229 by 229 mm (9 by 9 in.), with three 14 mm ( $9/16$  in.) diameter holes and three round-end slots 16 by 38 mm ( $5/8$  by  $1 1/2$  in.). Tolerances were  $\pm 0.81$  mm ( $\pm 1/32$  in.) on the blank outline, and  $\pm 0.13$  mm ( $\pm 0.005$  in.) on the pierced holes and slots. No burr limits were specified.

The steel rule was made of 12-point rule stock (4.32 mm, or 0.170 in., thick by 32 mm, or  $1 1/4$  in., wide) set full depth into hard plywood 16 mm ( $5/8$  in.) thick. A die plate of steel, which fit inside the rule, was used as the punch. The die was made by measuring a developed formed blank.

The ease and low cost of making a change in a steel-rule die proved important in this application because it was decided that one of the holes would not be needed. The punch that had been added for that hole was simply removed from the steel-rule die. After tryout, that hole was also eliminated in the conventional die before it was completed. The change, if made after the conventional die had been completed, would have cost much more.

The cost of the steel-rule die was 20% of the cost of the conventional die. Because the steel-rule die was fed and unloaded by hand, production was only a few pieces per minute. More than 1000 blanks were made in this steel-rule die.

**Template dies** (also called plate dies) are competitive with steel-rule dies in terms of cost and the quantity they can produce. Figure 18 shows an exploded view of the elements of a template die. Punches and die elements can be added, as in steel-rule dies, to combine piercing with blanking.

**Punch.** The punch or template (Fig. 18) is made to fit the outline of the blank to be produced. The punch is usually made of medium-carbon steel plate (1040, 1050, or 4140) or of

Fig. 16 Exploded view of a steel-rule die. See text for discussion.

ground flat stock such as O2 tool steel, on which the edges may be flame hardened. In more difficult applications or where longer life is needed, the punch can be made of D2 or equivalent tool steel and hardened.

**Die.** The die is usually assembled of doweled, hardened blocks of steel, ground to fit the punch with proper clearance. The same materials are used as for the punch.

**Construction.** Typical clearance for template dies is 0.076 mm (0.003 in.). The construction shown in Fig. 18 is satisfactory for blanking low-carbon steel in the same types of applications as steel-rule dies. For severe blanking, a template die can be made stronger by using one-piece construction or adding pins to prevent the die blocks from spreading, and by nesting the die or die segments into a recess in the die backing plate (subplate).

**Operation.** A continuous strip of stock can be fed into a template die, feeding the stock against a stop for each press stroke and using a side guide for the stock. Blocks of tough rubber are usually used as strippers (Fig. 18), pushing the blank back into the strip so that the blank is removed from the die by the feed motion of the strip. A typical application of template dies is described in the following example.

**Example 4: Blanking Laminations in a Template Die.** Motor laminations of 1.52 mm (0.060 in.) thick pickled hot rolled low-carbon steel were blanked in a template die. The blank measured 318 by 140 mm (12.5 by 5.5 in.). The punch was made of a one-piece template, except for inserts that were provided where changes may be needed. The die was made with 0.076 mm (0.003 in.) clearance all around the punch (template).

The die was made of D2 tool steel. Rubber blocks were used for strippers, which pushed the blank back into the skeleton in the vertical press so that the blank was unloaded by the feeding of the stock. Hand feeding produced fewer than ten pieces per minute.

The burr was approximately 0.051 mm (0.002 in.)—well below the specified limit of

0.102 mm (0.004 in.). Estimated die life was 100,000 pieces.

**Subpress dies** are short-run die sets that are attached to the press bed but in which the punch shoe is not attached to the ram. They require less setup time than conventional dies but have a lower production rate. The length of stroke of a subpress die is limited because springs are used to raise the punch. Subpress dies are sometimes used to blank the precision parts used in instruments and timepieces.

Self-contained notching tools can be purchased ready to install as subpress tools. Notching units, consisting of both punch and die mounted in individual C-frame units, are available in a variety of standard-corner, V, and square-edged sizes for notching low-carbon steel in thicknesses to 6.4 mm (1/4 in.). Special shapes of irregular outline can be incorporated into standard notching units. The notching units can be used singly or in groups, and they can be used in combination with piercing tools of similar construction.

Each unit is self-contained and self-stripping by means of springs. The punches are held in close alignment and are not attached to the ram of the press. Each unit is located, pinned, and bolted to a die plate, template, or T-slot plate and is mounted on the bed of any type of press or press brake of adequate shut height.

This type of subpress tool can be used to make small blanks, but it is more commonly used to notch and pierce precut blanks. The units can be reused to produce parts of different shapes by relocating the tools.

### Construction and Use of Conventional Dies

Conventional blanking dies consist basically of one or more mating pairs of rigid punches and dies and are the standard tooling for the production blanking of sheet metal in a press. Mating pairs of metal punches and dies are combined in various ways, and additional com-

ponents are added to make up compound, progressive, transfer, and multiple dies.

Conventional dies are costly, specialized tools that are generally used for only one product, but they are so efficient, accurate, and productive that they are typically the best method of mass production at the lowest cost per piece. They are occasionally used for short-run production when tolerances are exceptionally stringent or when other reasons make the use of short-run dies impractical.

Conventional dies are more accurate than most short-run tooling, and they retain their accuracy for a greater number of pieces. They can also usually be resharpened after wear has affected their action or the quality of the work. Before dies are worn out, they have generally been resharpened many times. Conventional dies commonly produce several million blanks before replacement.

**Tool materials** used for blanking low-carbon steel sheet in conventional dies include (in order of increasing lot size for which they are recommended) 1020 steel; W1, O1, A2, and D2 tool steels; and, for extremely long runs, carbide. For long runs on steel thicker than approximately 6.4 mm (1/4 in.), M2 tool steel is often used instead of carbide because of the limited shock resistance of carbide. Type D2 tool steel is probably the most commonly used and most widely available tool material for the mass-production blanking of steel and other metals.

Cold rolled sheet and hot rolled pickled-and-oiled sheet are far less damaging to tools than gritblasted or hot rolled unpickled surfaces. Tool materials that have a high resistance to abrasion, such as A2 or D2 tool steel, are recommended for use in tools for the blanking of sizable production lots of hot rolled unpickled steel. Detailed information on the selection of tool materials and on tool life is available in the article "Selection of Materials for Shearing, Blanking, and Piercing Tools" in this Volume.

**Single-Operation Dies.** The simplest conventional blanking dies are single-operation dies.

**Fig. 17** Steel-rule die that was used as temporary tooling for the blanking of low-carbon steel sheet 3.96 mm (0.156 in.) thick. Dimensions given in inches

**Fig. 18** Exploded view of a template die

They are used as separate units to produce blanks or as parts of more complex dies that perform several operations on a workpiece. The separate stations of a progressive die are similar to single-operation dies (although integrally constructed), and transfer presses use many single-operation dies.

The *drop-through die* is one of the most common types (Fig. 19). In this die, the severed blank is forced through the die opening by the downward motion of the punch, and it drops through into a chute or container. This type of blanking die has a minimum number of parts and is relatively inexpensive. Another major advantage of drop-through blanking dies is their simple and reliable blank ejection system, which is usually compatible with the use of this type of construction in progressive or transfer dies. In other types of dies, the ejection system may be more complicated than the die itself.

The disadvantages of drop-through dies for blanking include the following:

- Unless parallels are placed between the die and bolster, blanks must be small enough to go through the hole in the bed.
- Blanks may distort by dishing.
- Some shapes make drop-through difficult.
- The die must be on the lower shoe and the punch on the upper shoe of the die set.

Two other types of single-operation blanking dies—inverted and return dies—can be used when, because of size or susceptibility to damage, blanks or workpieces cannot be unloaded by dropping through the die but can be removed between the die and punch faces.

*Inverted dies* (Fig. 20) have the punch on the lower shoe and the die on the upper shoe. A knockout pin releases the blank from the die, and the blank is removed mechanically or manually from the top of the punch. A scrap cutter is usually included so that the scrap can be blown or knocked away. The scrap is sometimes allowed to stack up in successive collars around the punch and is stripped off manually after a number of pieces have been blanked.

*Return dies* (Fig. 21) are made in the usual way, with the punch on the upper shoe and the die on the lower shoe. The punch shears the blank and presses it into the die cavity, as with other

types of blanking dies. A spring-loaded pressure plate or die cushion acts as an ejector for the die, returning the blank to the surface of the die, where it can be picked off manually or mechanically. A spring-loaded plate on the upper shoe acts as a blankholder on the downstroke and as a punch stripper on the upstroke. Like many inverted dies, a variation of the return die shown in Fig. 21 includes a scrap cutter (not shown in Fig. 21) that parts the ring of scrap so that it can drop away, can be blown away, or can be removed mechanically.

Inverted and return dies have the advantage of not needing a clearance hole to let the workpiece or blank drop through. The main disadvantages of inverted and return dies are:

- They are more expensive than drop-through dies because they have more parts.
- They may require careful adjustment and synchronization of external ejectors and air blasts, which adds to setup costs.

Of the two types, inverted dies are generally simpler to construct and have less complicated knockout mechanisms than the pressure-plate or die-cushion ejectors in return dies.

Return dies are better suited to continuous strip operation because the strip remains in line and is not pressed down by the die over the punch. If the workpiece must be clamped before blanking, the blankholder or the pressure plate (or both) in a return die holds the workpiece or blank through the entire working stroke.

Fig. 20 Inverted blanking die with the punch on the lower shoe and the die on the upper shoe

Fig. 19 Elements of a conventional drop-through blanking die

Fig. 21 Return blanking die with spring-loaded pressure plate that acts as a die cushion and an ejector for the die

Instead of being removed by the methods described previously, the severed blank is sometimes pushed back (completely or partly) into the strip to be removed later, as is sometimes done in a progressive die. Pushback can also be used for other purposes, such as to provide knockouts for fitting in electrical panels or junction boxes and in other sheet-metal products. A flattening operation is sometimes added to assist pushback.

**Compound dies** perform several operations on the same workpiece in the same stroke of the press—such as blank and pierce, or blank, pierce, and form. Figure 22 shows the elements of a compound die for simultaneous blanking and piercing. In this die, the blanking punch is in the bottom; a hole in the punch is used as the piercing die. The piercing punch and the blanking die are in the top.

Compound dies are generally more economical in mass production than a series of one-operation dies, and they are usually more accurate. For example, a compound die that blanks and pierces a workpiece can hold the spacing between pierced holes or the relation of the pierced hole to the edge of the blank more accurately than would be possible if the individual operations were done in separate dies. This is because of possible variation in locating the blank for piercing or in locating a prepierced strip for blanking.

Fig. 22 Elements of a compound die for simultaneous blanking and piercing

Because the complexity of operation causes greater difficulties in unloading the workpiece, compound dies usually run slower than single-operation dies; the maximum speed of a compound die is approximately 250 strokes per minute. Other disadvantages of compound dies in comparison to single-operation dies are that they are more specialized (so that a change in the product is more likely to make the die obsolete) and that initial and maintenance costs are both higher. An advantage of compound dies is that, because of their slower operation, they generally produce more pieces per sharpening than single-operation dies.

A complex compound die can sometimes be more economical than two simpler compound dies in making the same part. This is illustrated in the following example.

**Example 5: Replacing Two Two-Operation Dies with a Four-Operation Die.** The cup shown in Fig. 23 was originally produced from annealed cold rolled low-carbon steel in two compound dies in separate press operations. The first die was a blank-and-draw die; the second was a pierce-and-pinch-trim die. Two separate dies were used on the assumption that the large pierced hole in the cup would not leave enough tool thickness to sustain all four operations. A 400 kN (45 tonf) open-back inclinable press was used for each of the two operations at a production rate of 500 pieces per hour.

**Fig. 23** Cup that was blanked, drawn, pierced, and trimmed in a compound die. This part was previously made in two compound dies: blank and draw, and trim and pierce. Dimensions given in inches

**Fig. 24** Brake-drum back that was produced in two press operations, in a blank-and-notch die and in a restrike-and-form die. Dimensions given in inches

Examination of the procedure led to the design of a die to blank, draw, pierce, and trim—all in one press stroke. The same press was used at the same speed, thus cutting the labor cost per piece in half. Tooling cost also was reduced because the cost of the new die was less than the combined cost of the original two dies.

**Production Applications.** The following example describes production applications in which compound dies were used for blanking and other operations because of their inherent accuracy.

**Example 6: Blanking, Forming, and Piercing a Brake-Drum Back in Compound Dies.** An automobile brake-drum back (Fig. 24) was formed from hot rolled 1012 steel in two press operations. A compound die was used to blank and notch the part in a 1.8 MN (200 tonf) press at the rate of 17½ strokes per minute, making one part per stroke. The tolerances shown in Fig. 24 were maintained in production with ordinary shop practice, as was the tolerance on the 14° 24' angle ( $\pm 0^\circ 30'$ ). The die, made of vanadium tool steel, required reworking after 50,000 pieces. Chlorinated oils were used as lubricant.

In the second press operation, a compound die in a 3.6 MN (400 tonf) press formed the workpiece, pierced the center hole, and flattened the workpiece at the notches. This die was made of tungsten oil-hardening tool steel. Production rates, lubrication, and die life were the same as in the blank-and-notch operation.

**Progressive Dies.** In a progressive die, the workpiece, while attached to the strip (or to the scrap skeleton), is fed from station to station at each stroke. At each stroke, the die performs work at some or all of the stations. The workpiece is cut off and unloaded at the last station. Each station can be simple or compound. Figure 25 shows the principal parts of a two-station blank-and-pierce progressive die.

In producing the simple blank shown in Fig. 25 from coiled strip in a progressive die, the round hole is pierced at the first station. The strip is then fed left, to the next station. There, the pilot enters the hole as the blanking punch moves

**Fig. 25** Principal components of a two-station blank-and-pierce progressive die. Pierced blank and work metal (steel strip) are shown at top. The use of a pilot in the pierced hole ensures accuracy to within a few thousandths of an inch.

down to complete the blank. Accurate relation of the hole to the outline of the blank depends on accurate fit of the pilot in the hole. The completed part is not separated from the strip until the last operation, regardless of the number of operations. After the first piece, one piece is completed at each stroke.

A progressive die is expensive, and because it is usually set up in an automatic press with scrap cutter, feeder, straightener, and uncoiler, the total cost of the auxiliary equipment is also high. Other disadvantages of progressive dies are:

- The part cannot be turned over between operations.
- Material may be wasted because the workpiece may not nest well in the strip layout.

Coil stock (or, less often, flat strip stock) is used. Many operations on parts of small and medium size can be done in conjunction with blanking in a progressive die, but the planning may be complicated. Soft or thin stock may be troublesome because the pilot may distort the locating holes. Setup and maintenance may be difficult.

The following example describes an application in which a progressive die was preferred to a compound die because it was too difficult to cut sharp corners in the compound die.

**Example 7: Change from a Compound to a Progressive Die to Cut Sharp Corners.** Figure 26 shows a fast-idle cam on which the corners had to be sharp. A progressive die was used because it was difficult to make and maintain sharp corners in a compound die. The part was blanked from coiled 1010 steel strip, 3.05 by 60 mm (0.120 by 2⅜ in.), with maximum hardness of 55 HRB. A seven-station progressive die cut the steps in the cam.

The punches were made of M2 tool steel and hardened to 60 to 63 HRC, and the die and the punch holders were made of O1 tool steel and hardened to 56 to 58 HRC. Approximately 10,000 to 15,000 cams were made between sharpenings of the progressive die, using a punch-to-die clearance of 0.10 mm (0.004 in.). This die was mounted in a 530 kN (60 tonf) press that was run at 76 strokes per minute.

In another operation, the steps in the cam were shaved to remove die break so that surfaces were flat across the thickness. Tools were of the same materials as in the progressive die and had a life

**Fig. 26** Fast-idle cam on which sharp corners were cut in a progressive die. Dimensions given in inches

of 5000 to 6000 pieces between sharpenings. The shaving was done at 16 strokes per minute in a 360 kN (40 tonf) press. Finally, the cam was liquid carburized 0.08 to 0.15 mm (0.003 to 0.006 in.) deep and oil quenched to file hardness. Zinc plating (0.005 mm, or 0.0002 in., minimum thickness) and a chromate postplating treatment followed.

**Transfer dies**, in which separate workpieces are fed from station to station by transfer fingers, are used for blanking only when coil stock is used. Blanking is done at the first station and is followed by other operations.

Transfer dies are typically used for additional operations on precut blanks made in a separate press (blanks that permitted close nesting for best use of the stock). When equally high utilization of stock can be obtained, coil stock can be used in a transfer die, with blanking done at the first station.

Like progressive dies, transfer dies and their related equipment (presses, special attachments, and feeding devices) are expensive and are best suited to mass production. Production rates are high.

**Multiple dies** (also called multiple-part dies) make two or more workpieces at each stroke of the press. The workpieces can be pairs of right-hand and left-hand parts, duplicate parts, or unrelated parts. Punch height can be staggered to reduce shock and blanking noise. Such dies are used in mass production.

Multiple dies can be multiples of single-operation dies or multiples of compound dies. They generally cost only slightly more than similar dies that make only one part per stroke. A die that makes two parts per stroke may cost only 5% more than a die that makes only one.

Such dies are primarily used for blank-and-form sequences. Draw operations are more difficult to combine with blanking or other operations because of blankholder needs and slower draw operation. Unloading of the work is sometimes difficult.

The use of multiple dies depends on the size and shape of the workpiece, size of the press, production quantity, possible savings in material and labor, and costs for setup and maintenance. Advantages of multiple dies include savings in material by better blank layout, reduced labor costs, and increased production. Disadvantages include increased setup and maintenance costs.

It is often better to increase the production of a single-part die by some simple change, such as putting the die in a faster press, rather than to replace the single-part die with a multiple die. A multiple die may also have to be run slower than the simpler die if a press of greater force capacity must be used to provide ample force. The use of a multiple compound die to blank, pierce, and form three pieces per stroke is illustrated in the following example.

**Example 8: Blanking, Piercing, and Forming Three Pieces per Stroke in a Multiple Compound Die.** A multiple compound die was used to make a thick dished washer with

three flats equally spaced on the edge circle, as shown in Fig. 27. The part was made of hot rolled 1008 or 1010 steel,  $2.36 \pm 0.18$  mm ( $0.093 \pm 0.007$  in.) thick.

Operations in the compound die were blank, pierce, and form. The blanks were nested so closely in the stock layout that the pilot holes (half-circles) had to be notched in the edge of the stock. Three parts were made with each stroke of the die, and the parts were pushed partly back into the scrap skeleton so that they were carried out of the press for unloading. Production was 500,000 pieces per month. The die, made of D2 tool steel, needed to be resharpened after 150,000 strokes (450,000 pieces) and required reconditioning (replacement of some parts) after 3.5 million pieces.

## Operating Conditions

To achieve high productivity and low unit cost, most blanking is done in high-speed mechanical presses. Speeds as high as 1200 strokes per minute are used. The equipment for high-speed blanking ordinarily includes a short-stroke press, automatic feed devices, and dies designed for bottom ejection.

In most blanking operations, press speed is limited by the length of feed, which is governed by blank size, or by the relationship between the force capacity of the press and the load. The combination of blanking with forming or drawing in compound dies also restricts press speed. Blanking speed may be as low as ten strokes per minute in producing blanks that are extremely large or that present handling problems for other reasons.

Regardless of the number of strokes per minute, the velocity of the punch always approaches zero near the bottom of the stroke. Within the usual range for production work in conventional blanking dies, the speed of the press has little practical effect on the speed of the punch during the blanking portion of the stroke. This effect, however, is critical for fine-edge blanking. Punch speed is usually slower during fine-edge blanking on the order of 7.5 to 1.5 mm/s (0.3 to 0.10 in./s) during the interval while the punch is cutting through the work metal (see also the article "Fine-Edge Blanking" in this Volume).

**Lubrication** requirements are generally less critical for blanking than for forming or deep drawing; stock to be blanked is often fed into the press with no lubrication other than the residue remaining on the stock from the lubrication at the mill. The stock is sometimes coated with a light mineral oil or a light chlorinated oil. However, lubrication is important in dies that have close clearance between punches and stripper. At speeds of 40 strokes and more per minute, such dies must be lubricated constantly with a spray of light mineral oil to prevent galling of the punches in the stripper. Additional information on lubrication requirements in blanking is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

## Effect of Work Metal Thickness

Stock thickness affects the selection of material for dies and related components, as well as the selection of die type and design. The amount of shear and relief (angular clearance or draft) built into a blanking die and the amount of clearance between punch and die all depend on blank thickness.

Work metal thickness is also a factor in the selection of blanking method, handling procedure, and handling equipment. Blanking in a punch press is usually the fastest and most economical way of producing blanks thinner than approximately 6.4 mm ( $\frac{1}{4}$  in.) in medium or large quantities.

Plate stock, in thicknesses of 6.4 to 25 mm ( $\frac{1}{4}$  to 1 in.), is less frequently blanked in presses than sheet or strip. Blanks of such thick material are often made by gas cutting, sawing, nibbling, or routing instead of by shearing or by press operations; selection of the method depends primarily on plate thickness and production quantity.

Almost all blanks thinner than 3.2 mm ( $\frac{1}{8}$  in.), except for intricate shapes chemically blanked from foil, are produced with conventional dies in mechanical or hydraulic presses. In only two of the examples of commercial practice presented in this article was work metal thicker than 3.2 mm ( $\frac{1}{8}$  in.) (example 3: 3.96 mm, or 0.156 in., and example 9: 4.75 mm, or 0.187 in.).

Because of its strength and rigidity, material thicker than 3.2 mm ( $\frac{1}{8}$  in.) is seldom blanked from coil stock or in a progressive die. On the other hand, because of its lack of strength and extreme flexibility, material thinner than 0.51 mm (0.020 in.) generally requires special handling techniques. The articles "Piercing of Low-Carbon Steel," "Blanking and Piercing of Electrical Steel Sheet," and "Forming of Carbon Steels" in this Volume contain additional information on the effect of work metal thickness on processing.

Distortion is often a problem in blanking complex shapes from thin low-carbon steel sheet by repeated strokes of a notching die. Distortion of such parts can be minimized by the use of hardened stock and by performing the entire blanking operation in one stroke in a single die.

**Fig. 27** Dished washer that was blanked, pierced, and formed, three pieces per stroke, in a multiple compound die. Dimensions given in inches

## Accuracy

Blanking in conventional dies readily produces parts within a total tolerance of 0.051 to 0.254 mm (0.002 to 0.010 in.), depending on the accuracy of the dies and the condition of the press. The tolerances given in Table 4 in the article "Piercing of Low-Carbon Steel" in this Volume generally also apply to blanks. The total tolerances listed under the column head "Location" apply to the relationship of a point on the periphery of the blank to a hole or other reference feature on the blank; the values listed under "Size" apply to a diameter for round blanks or to a similar control dimension for other blank shapes.

The production of blanks to these tolerances is illustrated by the examples in this article and the article "Piercing of Low-Carbon Steel." The following example describes the use of a compound die to maintain a total (envelope) tolerance of 0.13 mm (0.005 in.) on the relationship of a cam surface to a hole.

**Example 9: Blanking and Piercing a Cam to 0.13 mm (0.005 in.) Total Tolerance on Cam Surface in Relationship to Hole Position.** A compound die was used to blank and pierce the cam shown in Fig. 28 so that the hole would be in accurate relationship to the cam surface. The die was made of A2 or equivalent tool steel and hardened to 62 HRC, and it had a clearance per side equal to 10% of the stock thickness.

The cam, used in the hinge mechanism of an automobile door, was blanked from hot rolled 1020 steel 4.75 mm (0.187 in.) thick. Samples of the cam were inspected with an optical comparator, which compared the relationship of hole and cam surface to an outline that showed the full 0.13 mm (0.005 in.) tolerance, as illustrated in Fig. 28.

In another operation, the cam surface was machined to remove die break so that the edge would be square. The cam was then case hardened.

The part was produced in a 1.4 MN (160 tonf) open-back inclinable press at 60 strokes per minute. A sulfur-base lubricant was used. Die life was 40,000 pieces per sharpening.

**Blanking and Piercing with Compound Dies.** Example 6 in this article describes other applications of compound dies in blanking and piercing to conventional tolerances. For parts made in a progressive die, the relationship of the blank outline to features of the part produced in other stations of the die depends on the accurate fit of the pilot in the pilot hole. Transfer dies ordinarily provide better accuracy than progressive dies because the positive location of separate parts can be more precise than the roll feeding of coil stock with pilots.

Holding close tolerances on parts made in a progressive die is particularly difficult on soft or thin material because distortion of the locating holes by the pilot is more likely. Handling problems that may contribute to excessive variation in location or dimensions are not usually encountered in transfer dies, except with blanks of extremely thin material. Shaving (see the

following section in this article) is used to improve the accuracy of blank outlines to meet close tolerances or to improve edge quality.

Short-run dies are generally less accurate than conventional dies. By using more accurate methods of constructing short-run dies, closer tolerances on blanked work can be obtained, but at some increase in die cost (see the section "Construction and Use of Short-Run Dies" in this article). Generally, making blanks by methods other than the use of dies in presses, except for machining or grinding, results in a lower level of accuracy.

## Shaving

Shaving is an operation that can be performed after blanking to give a smooth, square edge and greater accuracy than can be achieved in ordinary blanking. Shaving removes only the blanked edge—cutting away the deformed, broken, and burred edge that was left in blanking. The elimination of these irregularities and the removal of locally work-hardened metal minimize breakage of the work metal during subsequent flanging, particularly the flanging of holes. The scrap produced in shaving is so thin that it resembles the chips produced in finish machining, rather than the usual scrap that is produced in a press.

When shaving is planned for, a small amount of extra stock is left on the workpiece to be removed in shaving. Shaving can be done in a separate operation, or it can be included in one station of a progressive die.

The shaving operation produces a straight, square edge, generally to approximately 75% of the metal thickness. Two shaves make a better, straighter edge (to approximately 90% of the metal thickness) than does a single shaving operation. To eliminate rollover from blank edges, which requires the removal of a greater amount of stock, it may be better to consider machining the workpiece rather than shaving.

Punch-to-die clearances range from 0 to 1% of stock thickness per side. Sturdy guideposts in a heavy die set are necessary to maintain the close alignment needed to prevent damage to the punch and die.

Shaving causes more wear on a die than ordinary blanking, so that the die produces fewer parts per grind and needs more frequent maintenance. Slivers of shaving scrap (chips) can jam feeding mechanisms, can become embedded in

**Fig. 28** Cam that was blanked and pierced in a compound die within an envelope tolerance of 0.13 mm (0.005 in.) total indicator reading. Dimensions given in inches

workpieces, or can mar the punch and die surfaces if not removed after each press stroke. Because of these problems, special attention must be given to die design when shaving is included among the operations done in a progressive die, as illustrated in the following example.

**Example 10: Shaving in a Progressive Die.** In evaluating methods for high-volume production of the shaved low-carbon steel part shown in Fig. 29, the use of a single progressive die for all cutting and forming operations was projected as the most economical method, principally because this method would involve fewer operations and less handling than the other methods considered. However, two major problems were anticipated. First, the life of the shaving tools was expected to be much shorter than that of the other tools in the progressive die (which would have resulted in costly interruption of production to sharpen or replace the shaving tools), and, second, it appeared likely that misfeed could occur from jamming of the feeding mechanism by slivers of shaving scrap.

By designing the die and feeding mechanism to eliminate difficulties from these two sources, efficient and economical production was obtained. The tools were of A2 air-hardening tool steel, hardened to 54 to 58 HRC for the forming sections and to 60 to 62 HRC for the cutting sections. The shaving section was made with a replaceable insert to minimize downtime when sharpening was needed. Damage to the progressive die from an accumulation of shaving scrap was prevented by including in the die a stock stop (Fig. 29, station 3) and misfeed and double-thickness protectors.

The shaving was done in station 4, as shown in Fig. 29. The production rate was 80 pieces per minute in a 530 kN (60 tonf) mechanical press with a 50 mm (2 in.) stroke. Tolerance on most sections of the part was  $\pm 0.13$  mm ( $\pm 0.005$  in.). Additional information on the use of shaving to maintain close tolerances and to improve the quality of hole walls is available

**Fig. 29** Formed part on which a blanked edge was made smoother and more accurate by shaving (station 4) after notching (station 3) in a progressive die. Dimensions given in inches

in the article "Piercing of Low-Carbon Steel" in this Volume.

**Shaving allowance**, or the amount of stock to be removed from the workpiece, depends on the hardness and thickness of the blank. Generally, the smallest amount of stock that will produce the desired result is left for the shaving operation. Table 5 lists shaving allowances recommended by one manufacturer. When shaving only one edge of a blank, shifting of the blank can be reduced by shaving the opposite edge as well, even if not required for function.

**Setups for Shaving.** Shaving requires that the blank be accurately located over the die or the punch, because only a few thousandths of an inch of metal is removed by the operation (Table 5). Piloting pins, projecting from the punch, can engage holes in the blank to ensure proper location. If the holes are not included in the original design, it may be permissible to add them for locating purposes only.

If adding holes is not permitted, a locating device such as that shown in Fig. 30 can be used. The clamping arms engage the blank at suitable nesting points. When the punch descends, the shaved blank falls through the die. The position of the clamping arms is fixed by the two stop pins.

Operation of this die can be improved by the use of a spring-loaded ejector and pressure pad within the die opening. As the punch ascends, the ejector lifts the shaved workpiece above the die face, thus eliminating the fall through the die

block, which may result in dents or other surface defects.

## Burr Removal

The shape, height, and roughness of burrs must be controlled to some degree in nearly all blanking operations. Complete elimination of burrs is not possible, but their formation can be minimized by the use of proper clearance between punch and die and by good maintenance.

Exposed burrs on the finished part can be unsafe and unsightly. Burrs on some blanked work can cause difficulties in forming and can increase the rate of workpiece breakage and die wear. Burrs can be removed by grinding, which generally removes the burr and a portion of the work-hardened edge. Tumbling in a barrel is a common method of deburring small parts. Other deburring methods include chemical and electrolytic deburring, belt grinding, polishing, and ultrasonic methods, as described in *Surface Engineering*, Volume 5 of *ASM Handbook*, 1994. Hand scrapers can be used to remove burrs from irregular shapes or soft metal parts.

## Blanking in Presses versus Alternative Methods

**Fine-edge blanking** is primarily used where die break is unacceptable and would require

removal by subsequent shaving if conventional blanking were used. In fine edge blanking, there is no die break, and the entire wall surface of the cut is burnished (see the article "Fine-Edge Blanking" in this Volume). In fine-edge blanking, the stock is tightly locked against the die and forced to flow toward the punch, so that the part can be extruded out of the strip without fracture or die break. Die clearance is extremely small, and no further finishing or machining operations are necessary to obtain blank or hole edges comparable to machined edges, or to those that are conventionally blanked or pierced and then shaved (see also the section "Fine-Edge Blanking and Piercing" in the article "Blanking and Piercing" in this Volume).

**Milling** is applicable mainly for cutting stacked parts, for short runs, and for making parts that are subject to frequent design change. It substitutes an inexpensive template for a conventional punch and die.

**Chemical blanking** may be competitive with blanking in presses for intricate parts that are only a few thousandths of an inch thick. Combs for electric shavers, for example, are more frequently made by the chemical blanking of stainless steel than by mechanical blanking methods.

**Contour band sawing and gas cutting** may be competitive with blanking for stacked parts and thick material.

## Safety

In all blanking operations, as in all press operations, there are hazards to operators, repairmen, and personnel in the vicinity. No press, die, or auxiliary equipment should be considered operable until these hazards are eliminated by installing necessary guards and other safety devices. The operator and all persons working around the blanking operation should be instructed in all precautions for safe operation before work is started. Additional information is available in the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume.

# Piercing of Low-Carbon Steel

PIERCING is the cutting of holes in sheet metal, generally by removing a slug of metal, with a punch and die. Piercing is similar to blanking, except that in piercing the work metal that surrounds the piercing punch is the workpiece and the punched-out slug is scrap, while in blanking the workpiece is punched out. Additional information on piercing is available in the articles "Blanking of Low-Carbon Steel," "Fine-Edge Blanking," "Forming of Carbon Steels," and "Blanking and Piercing of Electrical Steel Sheet" in this Volume.

The term *piercing* is used in this article, and in related articles in this Volume, to denote the production of a hole by removing a slug of metal with a punch and die. However, some prefer the terms *punching* or *perforating*, limiting the term *piercing* to the use of a pointed punch that tears and extrudes a hole without cutting a slug of metal. The term *perforating* is also sometimes used in the special sense of cutting many holes in a sheet-metal workpiece by removing slugs with several punches.

Piercing is ordinarily the fastest method of making holes in steel sheet or strip and is generally the most economical method for medium-to-high production. Pierced holes can be almost any size and shape; elongated holes are usually called slots. The accuracy of conventional tool steel or carbide dies provides pierced holes with a degree of quality and accuracy that is satisfactory for a wide variety of applications. Piercing is primarily used when accurate holes are required and when the production lot is large enough to justify the tooling costs. Alternative methods are used for smaller production lots or for holes that have a diameter less than stock thickness. Examples of alternative methods are drilling (including electrochemical machining), milling and sawing, and electric-arc and gas cutting. For increased efficiency, all of these methods can be applied to work that is stacked or nested.

## Characteristics of Pierced Holes

Pierced holes are different from through holes that are produced by drilling or other machining methods. A properly drilled or otherwise machined through hole has a sidewall that is straight for the full thickness of the work metal, with a high degree of accuracy in size, roundness, and

straightness. The sidewall of a pierced hole is generally straight and smooth for only a portion of the thickness, beginning near the punch end of the hole; the rest of the wall is broken out in an irregular cone beyond the straight portion of the hole, producing fracture, breakout, or die break (Fig. 1).

The piercing operation typically begins as a cut that produces a burnished surface on the hole wall and some rollover (curved surface caused by deformation of the workpiece before cutting begins), as illustrated in Fig. 1. The punch completes its stroke by breaking and tearing away the metal that was not cut during the beginning of the piercing operation.

The combined depth of rollover and burnish is a measure of the penetration depth of the stroke, also shown in Fig. 1. This is the part of the stroke during which the cutting force is exerted, before the metal fractures or breaks away (Fig. 1).

The amount of penetration before fracture is commonly expressed as a percentage of the stock thickness. In general, the percentage of penetration depends more on the material than on other factors, such as punch-to-die clearance. Table 2 in the article "Blanking of Low-Carbon Steel" in this Volume shows the average percentage of penetration (before fracture) in various metals under typical piercing or blanking conditions. The percentage of penetration affects energy consumption and cutting force in blanking or piercing, as described in the article "Blanking of Low-Carbon Steel" in this Volume.

## Quality of Hole Wall

If the sidewall of a pierced hole is not smooth or straight enough for the intended application, it can be improved by shaving in a die or by reaming. When done in quantity, shaving is the least expensive method of improving the sidewall of a pierced hole. Shaving in one or two operations generally makes the sidewall of a hole uniform and smooth through 75 to 90% of the stock thickness.

Superior accuracy and smoothness of hole walls can be obtained by fine edge piercing. With this method, one stroke of a triple-action press pierces holes with smooth and precise edges for the entire thickness of the material. Additional information is available in the article "Fine-Edge Blanking" in this Volume.

Burr height is an important element in hole quality, and a maximum burr height is usually specified. For most applications, the limit on burr height is between 5 and 10% of stock thickness. Burr height in piercing a given workpiece is primarily governed by punch-to-die clearance and tool sharpness.

Burr condition and limits usually determine the length of run before the punch and die are resharpener. With good practice, burr height generally ranges from 0.013 to 0.075 mm (0.0005 to 0.003 in.) but may be much greater, depending on workpiece material and thickness, clearance, and tool condition. As an alternative to limiting the length of run to control burr condition, unacceptable burrs can be removed by shaving or deburring.

## Selection of Die Clearance

Clearance, or the space between the punch and the sidewall of the die, affects the reliability of operation of piercing (and blanking) equipment, the characteristics of the cut edges, and the life of the punch and die. Published recommendations for clearances have varied widely, with most suggesting a clearance per side of 3 to 12.5% of the stock thickness for steel.

Establishment of the clearance to be used for a given piercing or blanking operation is influenced by the required characteristics of the cut edge of the hole or blank and by the thickness and the properties of the work metal. Larger clearances prolong tool life. An optimal clearance can be defined as the largest clearance that will produce a hole or blank having the required characteristics of the cut edge in a given material

Fig. 1 Characteristics of a pierced hole. Curvature and angles are exaggerated for emphasis.

and thickness. Because of differences in cut-edge requirements and in the effect of tool life on overall cost, clearance practices vary among plants and for different applications.

No single table or formula can specify an optimal clearance for all situations encountered in practice. Starting with general guidelines, trial runs using several different clearances may be needed to establish the most desirable clearance for a specific application. The following general principles are useful in making adjustments:

- Rollover (plastic deformation) and burnish depths are greater in thick material than in thin material and are greater in soft material than in hard material.
- Clearance (in decimal parts of an inch) needed to produce a given type of edge should vary directly with material thickness and hardness, and inversely with ductility.

All clearance values given in this article are for clearance per side, except where indicated.

## Edges

More specific guidance in selecting die clearances is provided by considering the types of edges produced with different clearances.

**Edge Types.** The acceptability of a punched hole or a blank is generally based on the condition of the cut edge and its suitability for the application. Usable holes and blanks can be obtained over a broad range of punch-to-die

clearances, each resulting in a different edge condition. Figure 2 shows five types of edges that result from the use of different clearances in piercing or blanking low-carbon steel at a maximum hardness of 75 HRB. The tabular data accompanying Fig. 2 include approximate ranges of fracture or breakout angles, rollover, burnish and fracture depths, and burr characteristics for the five edge types. Table 1 lists the clearance ranges that will produce these edges when piercing or blanking various metals.

*Type 1.* This type of edge has a large rollover radius and a large burr that consists of a normal

tensile burr in addition to bending or deformation at the edge. Burnish depth is minimal. Fracture depth is approximately three-fourths of stock thickness, and the fractured surface has a large angle. This edge is satisfactory for noncritical applications in which edge quality and part flatness are not important.

*Type 2.* This edge, which has a moderate rollover radius, normal tensile burr, and a small fracture angle, provides maximum die life and a hole or blank that is acceptable for general work in which a large burnish depth is not required. Burnish depth plus rollover depth is

**Table 1 Punch-to-die clearances for piercing or blanking various metals to produce the five types of edges shown in Fig. 2**

For clearances that produce type 1, 2, and 3 edges, it is ordinarily necessary to use ejector punches or other devices to prevent the slug from adhering to the punch.

Work metal	Clearance per side, % of stock thickness				
	Type 1(a)	Type 2	Type 3	Type 4	Type 5
Low-carbon steel	21	11.5–12.5	8–10	5–7	1–2

(a) Rollover plus burnish approximately equals punch penetration before fracture. (b) Burnish on edge of slug or blank may be small and irregular or even absent. (c) With spotty secondary shear. (d) In two separate portions, alternating with fracture. (e) With rough surface. (f) In two separate portions, alternating with burnish. (g) Amount of compressive burr depends on die sharpness.

**Fig. 2** Effect of punch-to-die clearance per side (as a percentage of stock thickness, *t*) on characteristics of edges of holes and slugs (or blanks) produced by piercing or blanking low-carbon steel sheet or strip at a maximum hardness of 75 HRB. Table 1 lists clearances for producing the five types of edges in various metals. See text for additional discussion and for applicability of the five types of edges.

approximately one-third of stock thickness; fracture depth, approximately two-thirds.

**Type 3.** This edge has a small rollover radius, a normal tensile burr, and a small fracture angle. It has low residual stress and is therefore particularly desirable for use in parts made of work-hardenable material that will undergo severe forming. The clean stress-free edge reduces the possibility of edge cracking during forming. Burnish depth plus rollover depth is one-third to one-half of stock thickness.

**Type 4.** This is a desirable edge for stampings used for mechanisms or parts that must receive edge finishing such as shaving or machining. The edge has a very small rollover radius, a medium tensile and compressive burr, and a small fracture angle. Burnish depth plus rollover depth is approximately two-thirds of stock thickness. This edge type can be recognized by the spotty appearance of secondary shear on the fractured surface.

**Type 5.** This edge has a minimum rollover radius and a large tensile and compressive burr, and it can be recognized by the complete secondary shear on the cut surface. It is useful in applications in which edges must have a maximum of straight-wall depth without secondary operations. On steel and other hard metals, die life is extremely short. The edge can be useful on some of the softer metals, which allow a reasonable die life.

**Edge Profiles.** The exact profile of the edge varies somewhat for different work metals, depending on the properties of the metal. Results are also slightly affected by:

- Face shear on punch or die
- Punch-to-die alignment
- Proximity to adjacent holes
- Distance to adjacent blanked edges
- Orientation of the different portions of the cut edge with respect to the rolling direction of the stock
- Ratio of hole size to stock thickness
- Internal construction of the die cavity
- Lubrication

The edge profiles illustrated in Fig. 2, as well as the estimates of fracture angles and the relative amounts of rollover, burnish, fracture, and burr given in the accompanying table, are intended to represent production conditions, allowing for the normal range of tool sharpness encountered in piercing and blanking low-carbon steel sheet.

The clearance values given in Table 1 for piercing and blanking various metals to produce the five types of edges were obtained in laboratory tests. The cutting edges of the punches were stoned to a radius of 0.05 to 0.15 mm (0.002 to 0.006 in.) to simulate an amount of wear corresponding to the approximate midpoint of a production run. No lubricant was used on the work metal.

As clearance is increased from the low values used for type 5 edges to those used for type 1 edges, several effects are evident. The edge profile deviates more and more from straightness

and perpendicularity as rollover, fracture angle, and fracture depth increase, while burnish depth decreases proportionately. Total burr height initially decreases as its compressive component decreases, leaving only the essentially constant tensile burr on type 2 and 3 edges (usually in the range of 0.013 to 0.076 mm, or 0.0005 to 0.003 in., depending on the work metal and the tool condition).

With further increase in clearance (edge type 1), bending or deformation at and near the edge adds an additional burr component, increasing the total burr height. This part distortion immediately adjacent to the cut edge is usually accompanied by a more gradual curvature, or dishing, on blanks or slugs; the corresponding curvature is much less pronounced on the stock around a hole, which is usually restrained by a stripper (curvature of blanks or stock strip is not shown in Fig. 2). At extremely large clearances (substantially above those shown for type 1 edges), double-shear characteristics are sometimes observed on the cut edge.

## Effect of Tool Dulling

The sharpness of punch and die edges has an important effect on cut-edge characteristics in piercing and blanking. At the beginning of a run, with punch and die equally sharp, the hole profile is the same as that of the slug or blank. As the run progresses, dulling of the punch increases the rollover and the burnish depth on the hole wall and increases the burr height on the slug or blank. Dulling of the die increases burnish depth and burr height on the hole edge. The punch dulls faster than the die; therefore, the changes in hole characteristics related to punch dulling proceed more rapidly than those related to die dulling.

On average, the following differences between hole edge and blank edge are observed in production work on sheet metal:

- Rollover is greater on hole edge than on slug or blank edge.
- Burnish depth is greater on hole edge than on slug or blank edge.
- Fracture depth is smaller (and fracture angle greater) on hole edge than on slug or blank edge.
- Burr height on hole edge is less than that on slug or blank edge, and varies with tool sharpness.

These differences are illustrated in Fig. 2.

## Use of Small Clearance

Where relatively square edges are required, small clearances can be used to produce holes with type 4 edges. Although tool life is shorter than when larger clearances are used, this may not be an important factor in the overall costs for short- or medium-production runs.

Figure 3 shows the ranges of die clearance per side used by one electronics manufacturer in

piercing and blanking three groups of metals up to 3.18 mm (0.125 in.) thick. The groups and the percentages of stock thickness on which these ranges of clearance were based are listed with Fig. 3. For stainless steel (not included in Fig. 3), nominal clearance per side was 2.5% of the thickness for stock thicknesses up to 4.75 mm (0.187 in.), and 4% for thicknesses between 4.75 and 6.35 mm (0.187 and 0.250 in.).

The data plotted in Fig. 3 were used by the manufacturer to determine whether a given punch and die could be used interchangeably for a metal different in thickness or type from the one for which it had been designed. If the point of intersection of a vertical line for the thickness of the new material with a horizontal line for the existing die clearance was within the range shown for the new material, the punch and die were normally satisfactory for use on the new material.

## Use of Large Clearance

Studies of die operation under both laboratory and production conditions have indicated that large clearances can be used to obtain maximum

Group	Clearance per side, % of stock thickness(a)	
	Average	Range
1. Aluminum alloys 1100 and 5052, all tempers	2.25	1.7–3.4
2. Aluminum alloys 2024 and 6061, T4 and T6 tempers; brass, all tempers; cold rolled steel, dead soft	3.0	2.25–4.5
3. Cold rolled steel, half hard	3.75	2.8–5.6

Note: Incorrect clearance values twice as large as those shown here have appeared with charts of this type in some publications, apparently because of confusion between clearance per side and total clearance. Also, stainless steel has erroneously been included with the metals in groups 2 and 3 in those publications.

(a) Percentages of stock thickness on which the ranges of acceptable clearance in chart are based. See text for clearances used in piercing or blanking of stainless steel.

**Fig. 3** Ranges of punch-to-die clearance per side recommended by one manufacturer for piercing and blanking of various metals up to 3.18 mm (0.125 in.) thick

tool life in numerous piercing (and blanking) applications. Table 2 indicates the effect of clearance on force requirements for piercing and stripping, presenting data on the test piercing of 6.53 mm (0.257 in.) diameter holes in cold rolled low-carbon steel of various thicknesses and hardnesses. Although individual results show some inconsistency, as would be expected because of the difficulty in obtaining accurate measurements of this type, the trend toward lower stripping force with an increase in clearance is evident from these data. The amounts of punch penetration into the die needed to release the slug are also given in Table 2. Table 3 lists production data on the effect of increased clearance on tool life for piercing and blanking common metals in various thicknesses.

On the basis of these studies and production experience, clearance per side equal to 12.5% of stock thickness has been recommended by some toolmakers and sheet-metal fabricators for the general-purpose piercing (and blanking) of cold rolled steel 0.51 to 3.18 mm (0.020 to 0.125 in.) thick in all tempers. This practice produces type 2 cut edges (Fig. 2).

The advantages observed when using a clearance of 12.5%, instead of substantially smaller clearances (as for a type 4 edge), include the following:

- Total tool life and tool life between regrinds are considerably increased (Table 3). Punch wear, normally two or three times die wear, is

greatly reduced because the hole is larger than the punch size and because stripping wear is minimized.

- Load on the press may be slightly reduced (Table 2).
- Burr height is smaller at the beginning of a run and increases at a slower rate during the run.
- Distortion or waviness of the work surface is reduced, especially with closely spaced holes.
- Stripping force is reduced (Table 2), which partially accounts for the reduced punch wear.

The factors that must be considered in applying the 12.5% clearance include the following:

- A different clearance may be required for steel outside the thickness range of 0.51 to 3.18 mm (0.020 to 0.125 in.), for metals other than steel, or to meet critical edge-quality requirements.
- A spring-loaded stripper should be used instead of the positive or fixed type, and the slug or blank must be prevented from adhering to the end of the punch. These precautions are especially important in transfer dies.
- Hole size is larger than punch size, particularly with hard or thin materials.
- With clearance above 15%, slugs of some materials (for example, 1.3 mm, or 0.050 in., thick type 410 stainless steel at a hardness of 50 HRC) may be ejected from the die at high velocity—possibly requiring special safety precautions.

**Effect of Work Metal Hardness.** Data on edge characteristics versus punch-to-die clearance in piercing cold rolled low-carbon steel sheet of different hardnesses (tempers) are plotted in Fig. 4. These graphs illustrate the basic characteristics of the edges of pierced holes for the standard AISI tempers at various clearances per side up to 35% of stock thickness.

The data given in Fig. 4 were obtained in laboratory tests on stock 0.58 to 3.18 mm (0.023 to 0.125 in.) thick in the tempers shown. The cutting edges of the punches used were stoned to a radius of 0.1 mm (0.004 in.) to simulate mid-run wear, and no lubricant was used in the tests. Similar trends would be expected for the edge characteristics of slugs or blanks, except that rollover and burnish depth would be smaller and burr height would be greater.

## Clearance and Tool Size

In blanking, the die opening is usually made to the desired size of the blank, and the punch size is then equal to the die opening minus twice the specified clearance per side. Conversely, in piercing, the punch is usually made to the desired size of the hole, and the die opening is then equal to the punch size plus twice the specified clearance per side.

Clearance per side for blanking dies is ordinarily calculated from the desired percentage of clearance and the nominal thickness of the stock.

**Table 2 Effect of clearance on piercing and stripping force required for piercing 6.53 mm (0.257 in.) diameter holes in cold rolled low-carbon steel**

No lubricant was used.

**Fig. 4** Edge characteristics (burr height, hole-size deviation, burnish depth, and rollover depth) in the piercing of low-carbon steel of different hardnesses with various punch-to-die clearances. Curves are for the AISI tempers shown, corresponding to the following HRB hardness limits: No. 1, 98 and higher; No. 2, 70 to 85; No. 3 to 5, 75 and lower. Results in shaded areas are not closely reproducible and show trends only.

However, to keep the inventory of piercing tools from becoming too large, some manufacturers use a modified practice for stocking piercing punches and die buttons in commonly used diameters. Punches are ordered to size. Work metal thickness is classified into several ranges, and die buttons are ordered to the specified clearance per side for the median stock thickness of the range to which the work metal for the given application belongs.

Hole dimensions are slightly affected as the clearance is changed. When using clearances that produce a type 4 edge, the diameter of the pierced hole is approximately 0.013 mm (0.0005 in.) less than that of the punch used to produce it. By increasing the clearances to those for a type 2 edge, the hole size will be equal to, or approximately 0.013 mm (0.0005 in.) larger than, the punch diameter.

With tight clearances, the slug is wedged into the die cavity. As the clearance is increased, the wedging action decreases; consequently, the slug may be as much as 0.013 mm (0.0005 in.) smaller than the die cavity.

## Force Requirements

The force needed to pierce a given material depends on the shear strength of the work metal, the peripheral size of the hole or holes to be pierced, stock thickness, and depth of shear on the punch. The calculation of piercing force is the same as that for cutting force in blanking (see the article "Blanking of Low-Carbon Steel" in this Volume).

**Effect of Punch Shear.** Shear is the amount of relief ground on the face of a punch (Fig. 5). It is used to reduce the instantaneous total load on the tool and to permit thicker or higher-strength materials to be pierced in the same press. It distributes the total piercing load over a greater portion of the downstroke by introducing

**Fig. 5** Three types of shear on piercing punches. Angle and depth of shear are exaggerated for emphasis.

the cutting edge in increments rather than instantaneously.

Piercing force (but not contact edge pressure or total work done) varies with the amount of shear on the punch face. With the bottom of the punch flat and parallel to the face of the die, piercing takes place on the entire periphery at once, requiring maximum force. The load on the press and tools increases rapidly to a maximum after impact and then releases suddenly when piercing is completed. By grinding shear on the punch as shown in Fig. 5, the maximum load is decreased, but the punch travels correspondingly farther to complete the piercing. Load release is also somewhat less sudden.

Shear location is ordinarily selected so as to confine distortion to the scrap metal (slug). Thus, in piercing, shear is ground on the punch because the punched-out metal is to be scrap. Concave shear and double-bevel shear (Fig. 5) provide a balanced load on the punch. Scalloped shear, sometimes ground on round punches, also provides a balanced load on the punch. An unbalanced load may cause deflection and tool breakage or excessive wear.

The amount of shear is determined by trial. However, shear equal to one-third of stock thickness ( $t/3$ ) will reduce piercing force approximately 25%, and shear equal to stock thickness will reduce piercing force approximately 50%. Shear can be applied to punches for large holes but not to small-diameter punches, because they lack column strength.

When a number of small holes are being pierced and the press load must be reduced, the punches can be ground to different lengths. This enables the punches to start cutting at different times and reduces the maximum load. In selecting a press, it should be noted that the reduction in maximum impact load on the press achieved by staggering punch length or by using shear is not sufficient to enable the use of a press that is significantly lower in tonnage rating, strength, or rigidity.

## Presses

Presses used in piercing are the same as those used in other pressworking operations. Open-back gap-frame presses of the fixed upright, fixed inclined, or inclinable type are common. The stock can be fed from the side with minimal interference from the press frame, and the parts can be removed from the front by the operator or ejected out the back by gravity or air jets.

Adjustable-bed or horn presses are used for piercing holes in tubing and in the sides of drawn or formed shells and boxes. Adjustable-bed and gap-frame presses are generally rated at capacities of less than 1.8 MN (200 tonf).

Straight-side presses are commonly used for compound-die and progressive-die operations. Increased accuracy, speed, and stability are required for these operations.

The turret punch press is a special machine in which the punches and dies are mounted in

synchronized indexing tables. Several sets of punches and dies are mounted in the table, which can be manually or automatically indexed into operating position. A flat blank is pierced and notched in a turret punch press by positioning it under the operating punch and tripping the punching mechanism. The blank is secured to a free-floating table on which a template containing the hole pattern is also attached. Each hole size and shape is coded so that all such holes can be pierced before indexing a new punch-and-die set under the press ram. The table is moved so that a pin will drop into a hole in the template; this places the blank in the proper position for piercing a hole. After the holes of one size and shape have been pierced, a new punch and die are indexed into operating position, and piercing continues in this manner until the part is finished. Almost any size or shape of hole can be pierced, within the capacity of the machine.

Turret punch presses can be programmed for tape control for increased production. Turret movement can also be controlled semiautomatically or automatically on numerical control or computer numerical control (CNC) punch presses. A closed-loop direct or alternating current drive connected to both the upper and lower turret assemblies provides the automatic turret with either unidirectional or bidirectional movement. Selected CNC presses even offer an optimization feature that automatically determines the most efficient and most cost-effective punching sequence for a specific workpiece.

## Tools

A typical piercing die consists of:

- Upper and lower die shoes, to which punch and die retainers are attached
- Punches and die buttons
- A spring-actuated guided stripper (Fig. 6)

Small workpieces are generally pierced in compound dies that blank and pierce in the same stroke. Piercing is also done in the stations of a progressive die or a transfer die.

Any of these dies can be constructed as multiple dies, in which two or more workpieces are pierced at each stroke of the press. Additional information on dies is available in the article "Blanking of Low-Carbon Steel" in this Volume.

**Punches.** Figure 6 shows three types of punches used for piercing: conventional, standard quill, and telescoping-sleeve quill. Conventional punches are generally available with a standard maximum shank diameter of 25 mm (1 in.), and they can be used to pierce round, square, oblong, or rectangular holes that have a size and shape not exceeding 25 mm (1 in.) in diameter or a size and shape that can be machined or ground on the end of the shank, as shown in Fig. 6(a). Punch shanks are also available in other sizes and shapes. Standard-sized punch retainers, backing

plates, die buttons, and die button retainers are also generally available.

The head-type punch shown in Fig. 6(a) is held by a carefully positioned and ground punch retainer. This type of punch cannot be replaced without removing the retainer. Headless punches are available with locking devices that permit replacement without retainer removal.

A spring-loaded and guided stripper is incorporated into the die design. Conventional punches for small-diameter holes and accurately spaced holes are supported and guided by hardened bushings pressed into the guided stripper plate. Piloting punches can also be guided in the same manner. For larger punches that do not need guidance or support, clearance holes are drilled in the stripper plate, and guide bushings for both the punch and the plate are omitted.

Figures 6(b) and (c) show two types of quill punches that replace conventional punches when piercing conditions are more severe or when more support is required for the punch when piercing small-diameter and accurately spaced holes to close tolerances. The type shown in Fig. 6(b) was designed to hold and align a small-diameter punch. The quill containing a close-fitting

**Fig. 6** Typical piercing die, and three types of punches used. See text for discussion. Dimensions given in inches

punch is pressed into the punch retainer. The punch can easily be changed and still maintain the original alignment and fit in the retainer. A punch guide bushing is used in the stripper plate, and a hardened backup plate supports the head of the punch. Quills are available for punches with body diameters ranging from 1.0 to 9.52 mm (0.040 to 0.375 in.). The nib or end can be ground to a smaller diameter if desired.

The telescoping-sleeve quill punch shown in Fig. 6(c) provides complete support to small-diameter punches and eliminates the weaknesses encountered in other punch-mounting designs. The upper part of the sleeve is press fitted into the punch retainer; the lower part, into the guided stripper plate. The inside diameter of the sleeve will accommodate punch bodies ranging from 0.38 to 9.52 mm (0.015 to 0.375 in.) in diameter. However, a punch body at the larger end of the range and with a ground nib is suggested for best results. When piercing holes in printed circuit boards, a 2° cone-type taper is ground on the bottom surface of the lower sleeve to concentrate the holding and stripping force at the edge of the hole.

Quill punches have been used to pierce holes in low-carbon steel having a thickness up to twice the punch diameter. Supporting sleeves or quills can be used for long, narrow punches of rectangular, oblong, or other shape.

Piercing dies can be ground into a hardened die block, or they can be die buttons that are press fitted into a die retainer, as shown in Fig. 6(a). To coordinate the quill, guide bushing, and die button, the punch retainer, stripper plate, and die retainer can be clamped together and jig bored and ground at the same time. This is possible because the quill, guide bushing, and die button are available with the same body diameters.

**Guided Strippers.** For all three types of punches, the function of the guided stripper is threefold. On the downstroke, the spring-actuated stripper contacts the work metal ahead of the punches and acts as a holddown. On the upstroke, the metal is stripped from around the punches. The third function is to guide small punches. To ensure that the force at the points of contact and release is sufficient to accomplish the stripping, stripper springs must exert the calculated force in the open-die position (not just in the closed-die position).

**Self-Contained Tools.** Piercing tools can also be purchased as individual units consisting of frame, punch, die, and spring or hydraulic strippers. The self-contained unit is not attached to the press ram but is located, pinned, and bolted to a die plate, template, or T-slot plate mounted on the bed of any type of press having adequate shut height. The units can be reused by relocating, pinning, and bolting. They can be used singly or in groups and with notching units of the same construction. Punch and die sizes can be replaced as desired, and standard sizes and shapes are available for piercing thicknesses up to 19 mm (3/4 in.). The units are available in

various styles for the horizontal and vertical piercing of flat or flanged workpieces.

**Tool Materials.** The materials used for piercing punches and dies are selected to suit the service requirements. In general, the materials used are the same as those for blanking. See the article "Selection of Materials for Shearing, Blanking, and Piercing Tools" in this Volume for information on tool materials and tool life.

Piercing involving unusual shock and high impact may require a shock-resistant tool steel such as S7. As in blanking, M2 high-speed steel is used for long punch life, particularly in piercing thicker steel, or where high abrasion resistance is required. In Example 7 in this article, a cam-actuated punch made of an air-hardening tool steel was replaced by a punch made of low-carbon steel, carburized and hardened. This change increased tool life tenfold.

**Use of Single-Operation Dies.** Single-operation piercing dies are used:

- When piercing is the only operation to be performed
- When the holes to be pierced are so close to the edge of the work that the incorporation of a piercing operation into a compound die would weaken the die elements
- When the required accuracy or the sequence of operations prevents the inclusion of piercing in compound, progressive, or transfer dies

In large work, such as panels for automobiles, holes are often pierced in a separate operation for numerous reasons. For example, the holes may distort during forming, accuracy of position may be impaired if holes are pierced before forming, or separate operations may provide a more balanced work load and reduce maintenance.

As an example, when a hole is pierced and coined to a bevel with the same punch, coining extrudes an excessive burr between the punch and the die unless a close punch-to-die clearance is maintained. Die maintenance can be reduced by using separate piercing and coining dies.

## Use of Compound Dies

Compound dies are used for most piercing operations in which accuracy of position is important. Except for the production of small lots, the use of a compound die is usually the most economical method for making a pierced and formed part to commercial tolerances. The following example describes the use of a compound die to blank and pierce a U-shaped bracket before it was formed.

**Example 1: Piercing Five Holes with a Compound Blank-and-Pierce Die.** The mounting bracket shown in Fig. 7 was made of 4.55 mm (0.179 in.) thick hot rolled 1010 to 1025 steel strip, 200 mm (7 7/8 in.) wide, in two operations: blank and pierce, then U-form. A compound die was used to blank the outline and pierce three round holes and two slots. The holes were reamed to size in a secondary operation to

hold the 0.025 mm (0.001 in.) tolerance on the diameter. The compound die was made of oil-hardening tool steel (O2) hardened to 58 HRC. Punch-to-die clearance was 5% of stock thickness per side.

The blank was located by pins in the 8.7 by 14 mm (11/32 by 9/16 in.) slots for the forming operation. A spring-loaded pressure pad held the blank firmly against the punch during forming. To overcome springback, the flanges were overbent by 2 to 3°. The forming die was made of air-hardening tool steel (A2).

Total tolerance on location of the in-line holes was 0.25 mm (0.010 in.). Production lots were 50 to 100 pieces. Expected die life was 15,000 to 20,000 pieces before regrinding.

## Use of Progressive Dies

Progressive dies perform blanking, piercing, and other operations in successive stations of a die. Each station in a progressive die is similar to a simple die or a compound die. The workpiece in a progressive die remains connected to the strip of work metal until the last station in the die, so that the feeding motion carries the work from station to station.

In a progressive die, piloting holes and notches are pierced in the first station. Other holes can be pierced in any station if they are not affected by subsequent cutting or forming. Holes for which the relative position is critical are pierced in the same station; other holes are distributed among several stations if they are close together or near the edge of a die opening. Tolerances on hole shape, size, or location dictate whether holes are pierced before or after the part is formed.

It is often advisable to add idle stations or to distribute the work over one or two additional stations, so that holes will not be pierced near the edge of a die block. The die block is therefore stronger, and there is less chance of the die cracking in operation or fabrication. Adding stations also allows better support for the piercing punches and increases strength to the strip.

Progressive dies are more expensive than a set of single-operation dies for the same part; therefore, progressive dies are generally used for high production. However, because one part is made at each press stroke, direct labor costs are greatly reduced, and one operator can often

**Fig. 7** Bracket that was blanked and pierced in a compound die before being formed. Dimensions given in inches

attend to more than one progressive die. Manufacturing costs can also be reduced by making a pierced and formed part in a progressive die, rather than in two separate dies (one compound and one single-operation die).

The amount of scrap produced in progressive dies is generally high because the nesting of parts is somewhat limited and because material must be provided for connecting tabs and carrier strips. A fully automatic press with cutoff, feed, straightener, and coil cradle or reel is normally used with a progressive die; therefore, press costs are high. Pierced parts can sometimes be made most economically in a progressive die by using coil stock that is the exact width of the developed blank. In the following example, the high-volume production of a bracket in a progressive die is compared with the production of smaller quantities in separate operations in utility tooling.

**Example 2: Producing a Bracket in Large Quantities in a Progressive Die and in Small Lots with Utility Tooling.** Figure 8 shows a bracket and the strip development for producing it in a five-station progressive die in a 670 kN (75 tonf) mechanical press that had a 102 mm (4 in.) stroke, an air-actuated stock feeder, and an automatic oiler. Material for the bracket was coiled cold rolled low-carbon steel strip, 2.41 mm (0.095 in.) thick by 135 mm (5 1/4 in.) wide, in the No. 2 (half-hard) temper.

The die was made of D2 tool steel and hardened to 59 to 60 HRC. Setup time was 1.5 h, and the press was stopped for die maintenance at intervals of 15,000 pieces. Production rate was 1200 pieces per hour. A light paraffin oil was the

lubricant. The tolerance on the dimensions of all of the pierced holes was  $+0.051$ ,  $-0.025$  mm ( $+0.002$ ,  $-0.001$  in.), and the tolerance on the position of the square hole and the two rounded slots was  $\pm 0.13$  mm ( $\pm 0.005$  in.).

Small quantities of the brackets were made from coil stock 29 mm (1 in.) wide in the following operations, using utility tooling:

- Cut stock into 135 mm (5 in.) lengths (3500 pieces per hour)
- Trim end in a single-operation die, two strokes per piece (1000 pieces per hour)
- Pierce two holes 10.1 by 13.3 mm (0.398 by 0.523 in.), one at each end, in a single-operation die, two strokes per piece (1000 pieces per hour)
- Pierce a 4.88 mm (0.192 in.) wide slot and a 5.11 mm (0.201 in.) square hole, and lance and form two ears, all in a compound die for accurate relative position (2000 pieces per hour)
- Bend the ends down, locating on the ears (1000 pieces per hour)
- Drill four holes 4.90 mm (0.193 in.) in diameter in a multiple-spindle drilling machine (500 pieces per hour)
- Drill small hole next to square hole (500 pieces per hour)

The short-run method required eight times as many man-hours per 1000 pieces as the progressive-die method, and the brackets produced were less accurate.

## Use of Transfer Dies

Transfer dies are used for piercing in applications that are similar to those for which progressive dies are used. A number of operations are done in successive stations of the transfer die.

Blanking, cutoff, lancing, notching, forming, and drawing (as well as piercing) can be done in transfer dies. The method differs from progressive-die operation in that the workpiece does not remain attached to the strip for feeding but is fed from station to station by transfer fingers. Production quantities must be large enough to justify the cost of tooling and equipment.

**Accuracy** in the dimensions between pierced holes is highest for holes that are pierced by the same die in one press stroke. Accuracy in the

location of holes relative to an edge or some other feature is highest when the workpiece is blanked and pierced (or pierced and trimmed) in the same stroke in a compound die.

When the aforementioned procedures are used, total tolerances of 0.25 mm (0.010 in.) on hole location and 0.13 mm (0.005 in.) on hole size are readily met in normal production, and closer tolerances can be met with suitable tools, as indicated in Table 4. Tooling cost and per-piece cost usually increase in piercing to closer tolerances. Accuracy is typically somewhat lower for holes pierced by different dies or in different stations of a progressive or transfer die because of piloting and nesting tolerances.

Tolerances smaller than the lowest given in Table 4 can be met with the use of special tooling and gaging and close control over the press operations, but only at increased cost and a lower production rate. The use of shaving to produce holes to a tolerance of less than 0.025 mm (0.001 in.) in size is described in Example 11 in this article. The use of fine-edge blanking for improved accuracy and edge quality is discussed in the article "Fine-Edge Blanking" in this Volume.

Accuracy of hole location is increased by the use of a rigid stripper, precisely aligned on guideposts, to guide the punches. Typical clearance of round punches in the stripper (using drill bushings as guides) is 0.005 to 0.013 mm (0.0002 to 0.0005 in.) total. Lubrication is important in dies that have such close clearance between punches and stripper. At speeds of 40 strokes and more per minute, the die must be lubricated constantly with a spray of light machine oil to prevent galling of the punches in the guides.

Accuracy often requires that holes be pierced after forming. In some cases, it may be necessary to pierce a hole after forming in order to avoid distortion of the hole. In Example 8 in this article, holes on opposing flanges were cam pierced in one stroke after forming for accurate alignment. In Example 7, two slots were pierced in flanges after forming, instead of being machined, for accurate alignment and location.

**Noncritical holes**, for which there are no close tolerances on size or spacing, can be pierced for venting (to provide for free passage of air or other fluids), for lightening, for improved bond with a molded plastic cover, for increased flexibility of a workpiece, and even to provide

**Fig. 8** Bracket that was produced more economically and more accurately in a progressive die (strip layout shown) than by the separate-operation method used for small quantities. Dimensions given in inches

**Table 4** Typical accuracy in piercing

For holes that are pierced with a conventional die in the same press stroke. Location will be less accurate for holes that are pierced with different dies, or pierced in different stations of a progressive die or a transfer die.

Finish on tools	Die retainers used		Total tolerance on pierced holes			
			Location(a)		Size(b)	
	Typical material	Locating holes for tools	mm	in.	mm	in.
Commercial ground	1020 or 4130(c)	Drilled in a drill press	0.25	0.010	0.13	0.005
Commercial ground	1020 or 4130(c)	Jig bored and jig ground	0.10	0.004	0.13	0.005
Precision ground	4130(d)	Jig bored and jig ground	0.05	0.002	0.03	0.001

(a) Relationship between hole centers or between hole center and edge or other reference points on the workpiece. (b) Diameter for round holes, or other control dimension for holes of other shapes. (c) Can be hardened; other grades of steel also can be used. (d) Hardened and tempered before being jig ground

controlled strength. In the following example, noncritical holes were pierced to weaken a part so it would deflect under impact or shock loading.

**Example 3: Piercing Noncritical Holes.** The workpiece shown in Fig. 9 is a wheel spider that was designed to be enclosed in molded plastic and to deflect under impact load. The spider was made of hot rolled 1008 or 1010 steel, dead soft, pickled and oiled. The steel strip, 3.2 mm ( $1/8$  in.) thick by 406 mm (16 in.) wide, was hand fed into a two-stage progressive die in a 4 MN (450 tonf) mechanical blanking press. In the first stage, noncritical holes were pierced to make the spider deflect upon impact and to provide a better bond with the molded plastic. The piece was blanked in the second stage. The pierced blanks were then fed into a 5.3 MN (600 tonf) mechanical forming press, where the part was formed. The forming die was sprayed with soluble oil.

## Hole Size

Pierced holes can be of almost any size, ranging from holes as small across as the thickness of the stock to the largest size that can be adapted to the equipment available. Some holes can be pierced that are smaller across than the stock thickness, but such piercing is not common.

Small holes and slots are pierced in much the same manner as large holes, but small holes are more difficult to pierce because slender punches are comparatively weak. To minimize deflection and breakage, punch length is limited to that needed for the operation, and punches are specially stiffened and guided (Fig. 6). The minimum hole size that can be pierced in a specific application is ordinarily found by trial.

## Piercing of Thick Stock

The effects of work metal thickness on piercing are generally the same as on blanking.

**Fig. 9** Wheel spider in which noncritical holes were pierced for deflection under impact and to improve bonding to plastic. Dimensions given in inches

Cutting force increases with thickness; consequently, tool design and material, press selection, and operating conditions are influenced by work metal thickness. The relationship between die clearance and work metal thickness is discussed in the sections on die clearance in this article. The minimum pierced hole size is usually expressed as a function of work metal thickness, as described in the preceding section. The following example illustrates the piercing of unusually thick flat workpieces prior to forming.

**Example 4: Piercing a Square Hole in 19 mm ( $3/4$  in.) Plate.** A hole 17 mm ( $11/16$  in.) square was pierced through high-strength low-alloy steel plate 19 mm ( $3/4$  in.) thick in a die in a 1.1 MN (120 tonf) open-back inclinable press. The die was made to pierce holes one at a time in any of several flat workpieces. A typical workpiece size was 19 by 305 by 940 mm ( $3/4$  by 12 by 37 in.).

The production rate for piercing in D2 tool steel dies was 300 to 360 pieces per hour. Maximum yearly production was 1000 pieces.

After the holes were pierced, the workpiece was heated to 815 °C (1500 °F) and formed into a curved shape. The shape was used as a digger bucket—one of many that were bolted to a large wheel (digger rim) of a machine used for digging trenches for sewers and pipelines.

**Radial Piercing of Curved Surfaces.** The radial piercing of thick curved workpieces is done in the same manner as the piercing of flat workpieces, except that the die must be designed to accommodate the curved parts. The piercing of a hole through round stock, such as a radial hole through a cylinder, is done by using a die with a heavily loaded stripper, both of which fit the round shape of the workpiece. The round hole is then readily pierced with little bulging of the workpiece, even though the hole can be as large as 40% of the diameter of the workpiece. The center of the hole should be at a distance from the end of the workpiece that is at least equal to the work thickness (diameter of the rod).

## Piercing of Thin Stock

Because of its strength and rigidity, material thicker than 3 mm ( $1/8$  in.) is seldom blanked or pierced from coil stock or in a progressive die. On the other hand, material thinner than 0.5 mm (0.020 in.), because of its lack of strength and extreme flexibility, generally requires special

**Fig. 10** Shim that was pierced and cut off from thin coiled strip in a compound die. Dimensions given in inches

handling techniques. The following example describes the blanking of steel shims from thin coil stock in a compound die.

**Example 5: Piercing of Shims from 0.25 mm (0.010 in.) Strip in a Compound Die.** The shim shown in Fig. 10 was made from coil stock of cold rolled 1008 steel, 19 mm ( $3/4$  in.) wide by 0.25 mm (0.010 in.) thick, in a pierce-and-cutoff compound die. Thickness tolerance was +0, -0.025 mm (+0, -0.001 in.). The coiled strip was fed automatically from a stock reel by an air-operated slide feed into a 220 kN (25 tonf) open-back inclinable press that operated at 150 strokes per minute.

The die, made of oil-hardening D3 tool steel, produced 230,000 shims before it needed sharpening. Die life was indefinite because a thickness of 38 mm ( $1 1/2$  in.) had been provided for grinding allowance in repeated sharpenings in order to restore the cutting edge.

**Hole Spacing.** Recommended minimum spacings for pierced holes are given in Table 5. These minimum spacings apply when ordinary pressworking practices are followed, without confinement of the workpiece in the die or other special procedures to prevent distortion.

As noted in Table 5,  $S_5$  (the distance from the edge of a hole to the inside of a flange) can be reduced when the metal is relieved near the pierced hole (as by a slot) to prevent distortion of the hole in forming. Accuracy in the shape and location of pierced holes often demands that the holes be pierced after the workpiece has been formed.

When a round hole must be pierced so as to leave almost no metal between the edge of the

**Table 5** Recommended minimum spacings for pierced holes in flat and formed steel and nonferrous metal workpieces

Dimension	Work metal thickness ( $t$ ), mm (in.)	Minimum distance, mm (in.)
$S_1$ and $S_2$	<1.57 (0.062) 1.57–9.65 (0.062–0.380)	3.05 (0.120) 3.05 (0.120) (but at least 1.5( $a$ ))
$S_3$ and $S_4$	<0.81 (0.032) 0.81–3.18 (0.032–0.125) 3.18–9.65 (0.125–0.380)	1.52 (0.060) $2t$ 2.5 $t$
$S_5$	to 9.65 (0.380)	$1.5t + r(b)$

(a) For steel. Minimum for nonferrous metals,  $2t$ . (b) For flanges with no relief. Value for  $S_5$  can be reduced when work metal is relieved for bending (as shown at lower left above) to prevent distortion of the pierced hole in forming.

hole and the edge of the part, the hole can be cut through the edge in a keyhole shape that minimizes bulging and does not leave sharp points. In the following example, spacing between the keyhole and the end of the part was only 58% of the recommended spacing given in Table 5, and spacing for the round hole and the slot was only 50% of the recommended spacing. Confinement of the blank in the die prevented distortion at the keyhole and the slot.

#### Example 6: Piercing Holes at Less Than Recommended Minimum Edge Distance.

The flyweight shown in Fig. 11 was part of a centrifugal device used to release pressure. The part was made of hot rolled 1010 steel, pickled and oiled, 6.4 mm ( $1/4$  in.) thick. Preliminary design had a wall thickness of 2.4 mm ( $3/32$  in.) between the 11 mm ( $7/16$  in.) diameter hole and the edge of the part. The original tooling called for a compound die to pierce and blank the part completely in one press stroke. However, with the fragile punch required, it was impossible to hold the 8.00/7.87 mm (0.315/0.310 in.) dimension on the keyhole opening (detail A, Fig. 11).

Production was successful when the part was made in three separate dies, using the sequence of operations shown in the accompanying table. A keyhole punch was used to pierce the 11 mm ( $7/16$  in.) diameter hole. The hole-to-edge spacing was increased from 7.9 to 11.1 mm ( $5/16$  to  $7/16$  in.).

Distortion was minimized by confining the blank in a nest during piercing. In the compound die, the hole shown in detail A and the edge of the part were connected with a radius tangent to both. When the keyhole punch was used, the punch surface intersected the outer edge at a  $45^\circ$  angle—a change that did not interfere with the function of the part but avoided difficulty in making a transition radius tangent to the outer edge.

The hole to be reamed was pierced with a 5.74 mm (0.226 in.) diameter punch and a 6.25 mm (0.246 in.) diameter die. The hole was later reamed to 6.29/6.26 mm (0.2475/0.2465 in.) in diameter for nearly its full length and then deburred. This hole was perpendicular to the part surface within  $+0^\circ 45'$ .

## Effect of Forming Requirements

It is simpler to pierce holes in a flat sheet than in a part that has been formed. Holes near a bend radius (see the illustration in Table 5) are usually distorted when the part is formed. If distorted holes are unacceptable or if an accurate relation of holes to other features in a workpiece is specified, piercing must be done after forming.

Dies for piercing after forming are generally more complex, more expensive, and require more maintenance than dies for flat blanks. These dies often have cam-actuated punches.

In Example 9 in this article, when the part was U-formed after piercing, one hole closed in

during forming, resulting in an elongated hole. This deformation was taken into consideration during product design. The following two examples describe applications in which it was necessary to pierce holes after forming.

#### Example 7: Piercing of Accurately Located Slots after Forming.

Figure 12 shows a formed part that, because of close tolerances, should not be slotted before forming. The original procedure was to drill the holes and mill the slots to hold the alignment of the slots to the end radii and to the tongue within 0.08 mm (0.003 in.). Results from machining were unsatisfactory, and it became necessary to pierce the slots after forming in order to hold tolerances.

The size and shape of the part and the location of the slots precluded piercing from the outside. Piercing was done from the inside by two punches split on the centerline of the part and moved outward by cam action.

The original punches were made of air-hardening tool steel hardened to 58 to 60 HRC. Because of breakage, the maximum punch life was 10,000 pieces. Changing the punch material to carburized and hardened 1025 steel increased the average punch life to 100,000 pieces. Annual production was approximately 240,000 pieces in lots of 50,000 to 60,000.

#### Example 8: Cam-Piercing Holes in Opposing Flanges of a Formed Part for Accurate Alignment.

To maintain alignment of the two opposing holes in the automobile-frame control-arm bracket shown in Fig. 13, the holes were cam pierced in one press stroke after the part was

#### Sequence of operations

1. Shear 1–2 m (4–8 ft) long by 100 mm ( $37/8$  in.) wide
2. Blank outline; pierce round hole (1000 pieces/h)
3. Ream and deburr round hole (300 pieces/h)
4. Pierce keyhole and oval slot (770 pieces/h)

#### Operating conditions

Types of press	670 kN (75 tonf) mechanical
Press speed	55 strokes per minute
Die material	A2 tool steel at 58–60 HRC
Lubricant	Sulfur-base, EP type(a)
Production rate(b)	300 pieces per hour
Die life per grind	20,000 pieces
Total die life	1 million pieces

(a) EP, extreme pressure. Applied to strip by roller. (b) Lot size was 2500 pieces; annual production, 10,000 pieces.

**Fig. 11** Flyweight in which holes were pierced at less than recommended minimum distances from the edge. Overall length of the flyweight was 90 mm (3.5 in.). Dimensions given in inches

formed. Tolerance on hole alignment was  $\pm 0.13$  mm ( $\pm 0.005$  in.).

The bracket was made of commercial-quality 1008 or 1010 steel, as-rolled, 3.78 mm (0.149 in.) thick, in five operations:

- Blank two workpieces per stroke
- Prebend, form, and re-form in three separate dies, side by side
- Form ear
- Trim in two stages
- Restrike and cam pierce

Blanking was done at 1800 pieces per hour in a 4.4 MN (500 tonf) coil-fed automatic blanking press. The remaining operations were done at 135 pieces per hour in a 2.7 MN (300 tonf) or a 3.6 MN (400 tonf) mechanical press.

The use of high-production equipment, including the cam-operated piercing die, was economical for the annual production of 350,000 pieces in 20,000-piece lots. Drilling would have been used for making the holes if 10,000 or fewer pieces had been needed per year to meet production requirements.

## Piercing Holes at an Angle to the Surface

For piercing holes that are not perpendicular to the surrounding surface, the workpiece is securely clamped to the die with a pressure pad, and the dies are usually ground to fit the contour of the part. The shape of the punch nose depends

**Fig. 12** Part in which accurately aligned slots were pierced (after forming) by two punches that were cam operated from the inside. Dimensions given in inches

**Fig. 13** Bracket in which accurately aligned holes on opposing flanges were cam pierced in one press stroke after forming. Dimensions given in inches

on the angle of contact with the workpiece and on the stock thickness.

In one application, holes 7.8 mm ( $\frac{5}{16}$  in.) in diameter were pierced in 6.35 mm (0.250 in.) thick 1090 steel at an angle of  $83^\circ$  to the surface. The holes were pierced by using sleeved punches and clamping the work tightly to the die with a pressure pad. In the following example, holes were pierced at an angle of  $40^\circ 30'$  to the surface of a flat workpiece, which was later formed by bending.

**Example 9: Piercing Holes at an Angle to the Work Surface.** Two 12.8 mm (0.505 in.) diameter holes were pierced at an angle of  $40^\circ 30'$  to the surface in the 2.67 mm (0.105 in.) thick cold rolled 1010 steel flat blank for the lamp-bracket base shown in Fig. 14. To pierce the compound-angle holes, the blank was placed in a nest, which held it at the proper angle and position for piercing. By repositioning the blank in a second nest, it was possible to pierce both of these holes with one punch and die.

The face of the die button was ground flush with the surface of the nest. The die had a straight land with a minimum length of 9.5 mm ( $\frac{3}{8}$  in.). There was a 16 mm ( $\frac{5}{8}$  in.) diameter relief below the land. The punch was ground with a step, as shown in Fig. 14. This step curled the slug, permitting the use of a long straight land in the die. The punch and die were made of M2 high-speed steel, hardened to 58 to 59 HRC. Punch-to-die clearance was 0.05 mm (0.002 in.) per side. Die life was 15,000 holes per grind.

The punch was mounted in a heavy quill designed for quick changing, which proved unnecessary. A spring-loaded pressure pad guided and added support to the punch and held the blank securely in the nest. The pressure pad was interlocked with the die so that shifting could not take place after piercing started. The die was run in a 90 kN (10 tonf) mechanical press, which produced 300 pieces per hour.

Before the angle holes were pierced as described previously, the outline of the part and seven  $90^\circ$  holes had first been produced in a compound blank-and-pierce die. The blanking die and punch, as well as the punches and die buttons for the  $90^\circ$  holes, were made of O1 tool steel and hardened to 59 to 60 HRC. The die was mounted in a 900 kN (100 tonf) mechanical press producing 300 pieces per hour. Die life was 40,000 pieces per grind.

When the workpiece was bent through  $180^\circ$  after all of the holes had been pierced, the 11.3 mm (0.445 in.) diameter hole changed in shape, assuming final dimensions of 10.4 by 11.3 mm (0.411 by 0.443 in.). This deformation did not affect the function of the hole.

## Special Piercing Techniques

Piercing operations that require special tooling and techniques include the piercing and forming of flanged holes, piercing with a fastener and with a pointed punch, and tube piercing.

**Flanged holes** (sometimes called extruded, countersunk, dimpled, or burred holes) are generally used for assembly purposes, such as providing more thread length for a tapped hole, greater bearing surface, or a recess for a flathead screw or rivet. The flanged hole can be produced by forcing a punch of the desired hole diameter through a smaller prepierced hole or by using a shouldered or pointed punch that both pierces the hole and flanges it.

The depth of flange that is formed depends on the elongation of the metal, and the flange is thinnest at its outer edge. A deeper flange can be made by extruding metal into the flange. Such flanging is done by first piercing a smaller lead hole and then using a punch that extrudes metal around the hole into the die clearance to produce a flange and simultaneously coins or forms a slight chamfer (depressed cone) or other shape of recess into the hole. This kind of extruded flange has uniform wall thickness. Such extrusion causes more metal flow and greater work hardening than ordinary piercing of flanged holes.

**Piercing with a fastener** (self-piercing) is primarily used as an assembly technique. A rivet, for example, can be used as a punch to pierce a hole through the material that it will join. The following example describes an application in which a square nut with a sharp face served as a piercing tool and then became part of an assembly.

**Example 10: Automatic Assembly of Self-Piercing Nut into a Bracket.** A square nut was automatically assembled into a body-bolt bracket, as shown in Fig. 15. The nut served as the piercing punch to make a 17.4 mm (0.687 in.) square hole in the embossed portion of the bracket. The bracket was made of galvanized, hot rolled 1006 steel, 1.9 mm (0.075 in.)

**Fig. 14** Lamp-bracket base in which two holes were pierced at an angle to the surface using the punch shown at lower left. All holes were pierced before the part was formed. The  $90^\circ$  hole in the U-bend zone deformed to an elliptical shape during forming. Dimensions given in inches

thick. After being pierced, the metal sprang back into two grooves in the nut, locking the nut into the pierced square hole. The nut was fed from a special installing head that was loaded from a rotary hopper.

Two assemblies were completed (pierced and installed) at each stroke of a 640 kN (72 tonf) open-back inclinable press running at 45 strokes per minute. Maximum daily production was 12,000 assemblies. The bracket was fed by a gravity-slide feed at the front of the press and was unloaded at the rear with the help of an air blast.

The 20.6 mm (0.812 in.) diameter hole was pierced at the same time the nut was inserted. Commercial punches and die buttons were used.

A standby unit for piercing a square hole was available in case a supply of the square nuts was not on hand when the part was scheduled to run. The nuts were later inserted and clinched using pneumatic equipment.

**Holes made with a pointed punch**, such as a cone-point, nail-point, or bullet-nose (ogive) punch, have rough or torn flanges. Such a hole is satisfactory for holding a sheet-metal screw, acting as a spacer, or providing a rough surface.

**Tube piercing and slotting** are done in dies when production lots are large enough to pay for special tooling. Simple dies, as well as more complex tooling such as cam dies, are designed to hold, locate, and pierce tubes, drawn cups, and other round parts.

A mandrel can be used in a horn die for work on tubing and other round parts as well as for piercing, slotting, and notching. One version of a die that uses a mandrel permits piercing two opposing holes in a tube in one stroke, with the slug from one wall going through a hole in the mandrel to act as the punch for the hole in the opposite wall.

Tubes can also be pierced with opposing holes without using a mandrel. The bottom half of the tube is supported by the die, which has a nest with the same diameter as the outside diameter of the tube. A similar nest for the upper half of the tube is in a combined holddown and punch guide. Therefore, the tube is completely surrounded during piercing. Because the bottom side of the tube is supported by the die, the lower hole is pierced without any distortion. The tube will collapse slightly around the hole in the top side of

**Fig. 15** Bracket with a square nut that pierced a hole for itself. Dimensions given in inches

**Example 12: Blanking and Piercing an Intricate Pattern.** The comb of an electric shaver (Fig. 18), made of pretempered spring steel, had an intricate pattern of slots and holes. Because more than 7 million of these combs were produced yearly, it was economical to construct the die needed to make them by blanking and piercing. Most of the dimensions on the part were held to a tolerance of  $\pm 0.025$  mm ( $\pm 0.001$  in.). Similar parts of stainless steel were made by chemical machining.

The stock was 56 mm ( $2\frac{3}{16}$  in.) wide high-carbon spring steel, pretempered to 42 to 48 HRC. Thickness was 0.11 to 0.12 mm (0.0045 to 0.0048 in.). Blanks sheared from the stock were 52.70 mm (2.075 in.) wide by 64.11 mm (2.524 in.) long and included, at each end, 12.1 mm (0.475 in.) that was later trimmed. This trimmed stock contained five tooling holes, one of which was a foolproof hole that prevented incorrect placement of the blank in the die.

In the first piercing operation, the rectangular slots at each end of the cutting areas were

pierced, along with the five 3.56 mm (0.140 in.) diameter tooling holes in the trim area and four ladder slots that bordered the three cutting areas. After this operation, the three cutting areas were ground to a thickness of 0.071 to 0.076 mm (0.0028 to 0.0030 in.). This ground surface, 15.9 by 12.6 mm (0.625 by 0.495 in.), tapered to the original stock surface in 4.11 to 4.62 mm (0.162 to 0.182 in.).

In the third operation, 0.46 mm (0.018 in.) diameter holes were pierced in the cutting areas at a centerline spacing of 0.572 mm (0.0225 in.) in one direction and 0.66 mm (0.026 in.) in the other direction. Each of the three cutting areas had 410 holes arranged in two panels of 205 holes each.

After the third operation, workpieces were deburred, and the area around each of the four ladder slots was coined to a depth of 0.019 to 0.038 mm (0.00075 to 0.0015 in.). The surface was buffed before plating, removing 0.008 mm (0.0003 in.) of stock. Finally, the comb was trimmed from the rough blank and four

1.6 mm (0.062 in.) diameter holes for locating studs and 22 rivet holes 1.24 to 1.26 mm (0.0487 to 0.0497 in.) in diameter were pierced. The piece was plated after assembly with the comb support.

Dies were made of D2 tool steel and hardened to 58 to 60 HRC. Some additional wear resistance that could have been attained by hardening to 60 to 62 HRC was sacrificed in order to make the delicate punches more resistant to shock. The presses were 620 and 670 kN (70 and 75 tonf) mechanical presses operated at 5 or 6 strokes per minute to accommodate meticulous hand feeding of the workpieces. Production lots consisted of 50,000 pieces each.

# Blanking and Piercing of Electrical Steel Sheet

ELECTRICAL STEELS are used for various static and rotating electrical devices. They are magnetically soft materials; that is, they are not permanent magnets but have properties that make them useful in electrical applications. Most of the parts produced from electrical steels must be laminated. A lamination consists of flat blanked sheets of a particular shape that are stacked to a given height and fastened together by riveting, bolting, or welding. Electrical steel sheet is available in coils or cut-to-length. For most applications, stock thickness ranges from 29 to 24 gage (0.343 to 0.607 mm, or 0.0135 to 0.0239 in.).

## Materials

The general category of magnetically soft materials encompasses many types of materials, including iron-nickel, iron-cobalt, and iron-aluminum alloys; ferrites; and austenitic stainless steels. The discussion in this article, however, is limited to the most commonly used magnetically soft materials: low-carbon electrical steels and oriented and nonoriented silicon electrical steels. Table 1 lists some of the characteristics and applications of these materials.

**Low-Carbon Steels.** For many applications that require less than superior magnetic properties, low-carbon steels (AISI 1010, for example) are used. Higher-than-normal phosphorus and manganese contents are often used to increase electrical resistivity. Such steels are not purchased to magnetic specifications. Although low-carbon steels exhibit power losses higher than those of silicon steels, they have better permeability at high flux density. This combination of magnetic properties, coupled with low price and excellent formability, makes low-carbon steels especially suitable for applications such as fractional-horsepower motors, which are used intermittently.

**Nonoriented Silicon Steels.** Except for saturation induction, the magnetic properties of iron containing a small amount of silicon are better than those of pure iron. Few commercial steels contain more than 3.5% Si because the steel becomes brittle and difficult to cold roll at silicon levels above 4%.

The commercial grades of silicon steel in common use (0.5 to 3.5% Si) are made primarily in electric or basic-oxygen furnaces. Non-oriented grades are melted with careful control of impurities; better grades have sulfur contents of approximately 0.01% or less. Continuous casting and vacuum degassing can be used. After hot rolling, the hot bands are annealed, pickled, and cold rolled to final thickness as continuous coils.

Semiprocessed grades of strip are not sufficiently decarburized for electrical use; therefore, decarburization and annealing to develop potential magnetic quality must be done by the user. This procedure is practical for small laminations accessible to the annealing atmosphere. Fully processed grades are strand annealed in moist hydrogen at approximately 825 °C (1520 °F) to remove carbon. The final annealing operation is very important and is carried out at a higher temperature (up to 1100 °C, or 2000 °F, for continuous strip) to cause grain growth and the development of magnetic properties. Use of a

protective atmosphere is vital. The steel often is coated with organic or inorganic materials after annealing to reduce eddy currents in lamination stacks.

Most finished nonoriented silicon steel is sold in full-width coils (860 to 1220 mm, or 34 to 48 in.) or slit-width coils, but some is sold as sheared sheets. All coils are sampled and tested according to ASTM A 343 and graded as to quality.

**Oriented Silicon Steels.** Grain size is as important in silicon steel as in iron with regard to core losses and low-flux-density permeability. For high-flux-density permeability, however, crystallographic orientation is the deciding factor. Like iron, silicon steels are more easily magnetized in the direction of the cube edge:  $\langle 100 \rangle$ . For special compositions, rolling and heat treating techniques are used to promote secondary recrystallization in the final anneal at approximately 1175 °C (2150 °F) or higher, which results in a well-developed texture with

**Table 1 Silicon contents, densities, and some applications of electrical steel sheet**

AISI type	Nominal Si + Al content, %	Assumed density, Mg/m <sup>3</sup>	Characteristics and applications
Low-carbon steel			
...	0	7.85	High magnetic saturation; magnetic properties may not be guaranteed; intermittent-duty small motors

...	2.9–3.15	7.65	Low core loss at high operating inductions

the cube edge parallel to the rolling direction {110} <001>. Conventional oriented grades contain approximately 3.15% Si.

In approximately 1970, improved {110} <001> texture was developed in silicon steel through the modification of composition and processing. The high-permeability material usually contains approximately 2.9 to 3.2% Si. Conventional oriented 3.15% Si steel has grains approximately 3 mm (0.12 in.) in diameter. The high-permeability silicon steel tends to have grains approximately 8 mm (0.31 in.) in diameter. Ideally, grain diameter should be less than 3 mm (0.12 in.) to minimize excess eddy-current effects from domain-wall motion. Special coatings provide electrical insulation and induced tensile stresses in the steel substrate. These induced stresses lower core loss and minimize noise in transformers.

**Size and Shape.** Flat laminations of a wide variety of shapes and sizes are blanked and pierced from electrical sheet. However, most are shaped like those shown in Fig. 1. Laminations similar to those shown in Fig. 1(a) can range in

diameter from less than 25 mm to 1.3 m (1 to 50 in.) or more, and laminations similar to those shown in Fig. 1(b) can range in length from less than 25 to 305 mm (1 to 12 in.) or more.

**Punchability.** Materials used for electrical sheet can be classified in the following order with respect to decreasing ease of blanking, piercing, and notching:

- Conventional flat-rolled low-carbon steels such as 1008
- Nonoriented silicon steels
- Oriented silicon steels

To a large extent, applications also follow the aforementioned classification (Table 1). Each group has certain distinct characteristics that affect punchability. In addition, differences in composition and hardness within any specific group cause considerable variation in punchability (see the section "Effect of Work Metal Composition and Condition on Blanking and Piercing" in this article).

## Presses

A general-purpose punch press in good mechanical condition is acceptable for stamping laminations, but large-volume production of laminations by progressive-die methods requires the use of high-productivity presses (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume). Most high-productivity presses have heavy bed and crown members to minimize deflection and vibration. Bed deflection for lamination presses should be no more than 0.006 mm/mm (0.006 in./in.) of bed length (measured left-to-right between uprights), with a load equal to the rated capacity of the machine distributed over two-thirds of the bed area between tie rod centers. Deflection of the slide should not exceed 0.006 mm/mm (0.006 in./in.) of the length between the pitman centers, with rated load evenly distributed between those centers. Bending deflection and shear deflection are both considered in these standards. Double-crank presses with two or four points of suspension are preferred for progressive-die applications because of their better resistance to off-center die loads. Parallelism of the bed and slide should be 0.012 mm/mm (0.012 in./in.) of bed dimensions, both left-to-right and front-to-back.

Presses designed for producing laminations have heavy connections, large diameters of the mainshaft and connection bearings, close gib clearances, and thick bolsters. Because of the close gib fits (needed for accurate vertical motion), recirculating oil systems must be used to provide forced-feed lubrication of bearings and slides.

The fact that a die was built with uniform punch-to-die clearance at all cutting edges does not necessarily mean that the clearance is uniform at the instant the punch begins to enter the work metal. The act of applying the load to the

work metal can cause lateral deflections in the die and press, which can change the clearances. To minimize these undesirable deflections, the mechanical condition of the press and die must be maintained at a high level. The total force capacity exerted at each stroke must be in proper relation to the force capacity of the press and to the type of press frame (some types of press frames will deflect laterally more than others). Close-fitting gibs and bearings are essential in minimizing lateral deflection. The die should be built with large guideposts and close-fitting bushings.

A preventive maintenance program must be established to ensure that all presses are kept in top condition. Special attention should be given to bearing clearances, the condition of the counterbalance springs or cylinders, and the parallelism of the slide.

## Auxiliary Equipment

When producing motor laminations in individual dies for each operation with upright or inclined presses, blanks can be loaded and unloaded manually. However, when individual dies are used for the simultaneous production of stator and rotor laminations, feeding and stacking equipment is necessary for optimal efficiency. The use of an inclined press is preferred because gravity assists in loading the die and removing the laminations. When progressive dies are used, automatic feeding and scrap-cutting equipment is required.

**Stock reels, cradles, and straighteners** are required when coil stock is used. Several types and sizes are available (see the article "Presses and Auxiliary Equipment for Forming of Sheet Metal" in this Volume).

**Feed Mechanisms.** In progressive-die operations, the common types of feed mechanisms, for example, single-roll or double-roll, hitch, grip, and slide, are used to feed strip or coil. Cam feed, which has a fixed feed length, is widely used for large-volume production. This method is accurate at high speeds because it eliminates the slippage that usually occurs in the overriding clutch-and-brake mechanisms of roll feeds.

Magazine feeds have a mechanism that ejects the blank from the bottom of a stack into the die or onto a magnetic belt or a chain feed. In inclined presses, the blank may slide by gravity into the die nest after leaving the magazine.

**Stacking.** Figure 2 shows a method that can be used for stacking laminations when each operation is done in an individual die. Blanks are fed to the press (inclined 35 to 45° to the rear) from a magazine feeder. Laminations drop from the press into a chute, where they are picked up by a driven elevating belt that conveys them to the stacking chute, from which they fall onto a stacking mast. Stacking masts are usually 380 to 915 mm (15 to 36 in.) high. The tops of the masts are either threaded or have tapped holes so that they can be picked up by handling machines

**Fig. 1** Typical laminations blanked and pierced from electrical sheet. (a) Laminations for rotating electrical machinery are blanked and pierced in single-station dies (Fig. 3) or progressive dies (Fig. 4). Slots can also be made in precut blanks, one at a time, with notching dies. (b) Typical laminations blanked and pierced from electrical sheet for application in units other than rotating machines. Dimensions given in inches

and moved to subsequent operations. The bases of the stacking masts are large or weighted to prevent the masts from tipping or falling when being loaded or moved to the assembly floor.

**Scrap disposal** is a major consideration in producing laminations. The removal of scrap from a trimming operation or the removal of slugs from piercing holes and slots requires consideration during die design. Scrap is discharged through holes in the die shoe onto chutes. The chutes convey the scrap into containers or into automatic scrap-conveying systems below the floor. When the die is in the upper shoe, a mechanically operated pan can be used to catch the slugs on the upstroke. The slugs are then ejected into a container on the downstroke.

## Dies

Single-station and progressive dies are both used for making laminations.

**Single-Station Dies.** Each single-station die performs one operation, and a set of dies for a lamination can be mounted in one press or in different presses. Simple laminations such as those shown in Fig. 1(b) are usually produced in

Fig. 2 Method for stacking laminations stamped in individual dies

Fig. 3 Sequence of operations for producing stator and rotor laminations using single-station dies. Operation 1, stock blanked and pierced; operation 2, stator lamination notched; operation 3, rotor lamination separated from stator lamination; operation 4, rotor lamination notched. Compare with Fig. 4.

one operation. More complex parts may require several operations. Figure 3 shows a typical sequence for the production of stator and rotor laminations in four operations.

Single-station dies can be used for punching any lamination, regardless of the size, composition, shape, or quality requirements. However, because production with single-station dies is relatively slow, the cost per piece is high for mass production. Laminations such as those shown in Fig. 1 can be produced in large quantities at a lower cost in progressive dies.

The size of the workpiece and the quantity required influence the degree to which operations can be combined and the complexity of any one die. For example, in Fig. 3, the slots made in operations 2 and 4 can be punched in one stroke in a multiple die for each operation if the die sections are strong enough. An alternative method is to punch the slots in 28 strokes with a single-notch die in a high-speed notching press equipped with an indexing mechanism. Single-notch dies are used in the production of laminations for the following reasons:

- Tool costs are lower, and the single-notch die can be used on several different laminations. The cost is sometimes less than 5% of that for a multiple die that can pierce all the holes and slots in one press stroke.
- Laminations more than approximately 380 mm (15 in.) in diameter are sometimes too large to be notched by any other method because of tool and equipment costs. However, many larger-diameter laminations are multiple pierced.
- Limited production does not warrant the cost of a multiple die.
- Available equipment must be used.

**Progressive dies** perform a series of operations at two or more die stations during each stroke of the press. Each working, or active, station in the die performs one or more operations. The work material progresses through successive stations until a completed part is produced (Fig. 4). Idle stations, in which no work is performed, are added to provide strength to the die, to facilitate material travel through the die, to simplify construction, or to increase flexibility for die changes.

One of the more common progressive dies used in the electric-motor industry is a five-

station die that produces a rotor lamination and a stator lamination with each stroke of the press (Fig. 4). This die can be provided with carbide inserts for the punch and die sections. It has a spring-actuated guided stripper. The die components are mounted on a precision die set with ball bearing guide bushings and hardened guide pins. Slender punches are guided through the stripper by bushings. Such a die usually has four active stations and one idle station.

The progressive die described previously is the blanking or scrap-all-around type. For the most efficient use of material, the cutting-off or parting methods of severing the blank from the strip are used where layout permits.

The principal advantages of progressive dies for blanking laminations are:

- Handling between operations is eliminated; therefore, cost per piece is lower.
- Laminations from progressive dies are generally stacked in chutes that allow the press to be operated at uninterrupted maximum capacity. Stacking chutes fastened to the bottom of the bolster or die shoe keep the laminations oriented in a smooth, uninterrupted flow from the die. Therefore, laminations are better controlled with regard to burr direction and are easier to handle for assembly.

Two disadvantages of progressive dies for blanking laminations are:

- A progressive die is, to a great extent, a single-purpose die. Even a minor change in part design can necessitate an expensive die alteration or can make the die obsolete.
- Progressive dies are more susceptible to damage from accidents than single-station dies. Progressive dies run at high speed and may make many strokes before the press can be stopped. Misfeed detectors built into the die can help prevent damage. Die damage can halt production in progressive operations. In single-station operations, if the inventory of processed material is sufficient to keep other dies running, a breakdown of a die does not interrupt production.

The minimum size of lamination that can be made depends on the slot size and spacing, work metal thickness, and tolerances on the slot dimensions. The die must be strong enough to withstand the blanking pressure. Figure 5 shows

Fig. 4 Blanking and piercing sequence for rotor and stator laminations in a five-station progressive die. Two pilot punches were used at each station. Station 1, pierce pilot holes, rotor slots, and rotor-shaft hole; station 2, pierce stator rivet holes and blank rotor; station 3, pierce stator slots; station 4, idle; station 5, blank stator. Compare with Fig. 3.

some very small laminations that were made in progressive dies. The 6.48 mm (0.255 in.) diameter rotor was made in three stations in order to have the necessary die strength. Part tolerances were such that piercing in three stations produced acceptable parts.

The dies for producing laminations are usually of segmented construction, which provides maximum accuracy. However, electrical discharge or electrochemical machining methods have been used to produce satisfactory dies.

There is no agreement as to the maximum size of lamination that can be efficiently produced in progressive dies. However, progressive dies are seldom used for laminations larger than 380 mm (15 in.) in major dimension. The factors that limit the maximum practical size are as follows:

- Progressive dies for making laminations more than 380 mm (15 in.) in major dimension represent a large investment (and a significant loss if damaged).
- Quantity demands are usually lower for large laminations; therefore, the investment is not warranted.
- Extremely large dies may require a press capacity that is so large as to be impractical.
- Problems from camber and lack of flatness in the stock are magnified in stamping large laminations in progressive dies.

## Selection of Die Materials

Almost any hardened tool steel is satisfactory as die material for making a small quantity of

laminations. However, for production blanking and piercing, either a high-carbon high-chromium cold work tool steel, such as AISI D2, or carbide must be used to resist the abrasiveness of electrical steels.

The shape or size of the lamination seldom affects the choice of die material. Dies ranging from the smallest to the largest and from the simplest to the most complex have been made from both high-carbon high-chromium tool steel and carbide. In addition, both die materials have been used to blank and pierce all compositions and thicknesses of electrical sheet. The composition and thickness of the stock rarely affect the choice between carbide and tool steel.

**Production Quantity.** If the dies are of the same design and construction, the total quantity of parts to be produced is the major factor in choosing die material. If the run is so short that it can be made with tool steel dies without sharpening, tool steel is more economical. However, for longer runs, carbide dies have 10 to 20 times as much life per grind as tool steel dies.

**Uniform quality of cut edges** and minimum burr height will be retained over a much longer run by carbide dies than by tool steel dies. In some cases, the edge condition of the lamination is not critical. However, when automatic stacking and core assembly equipment is used after blanking and piercing, burr height is important. Excessive burr height can cause short circuiting of the laminations in the core.

**Cost.** Depending on size and design, a die with carbide cutting edges will cost at least 1½ times as much as a steel die. However, in terms of cost per piece, carbide dies may be more economical. Press downtime and die maintenance affect cost per piece; carbide dies can run approximately ten times as long per sharpening as tool steel dies.

**Press condition** is important in the operation of blanking and piercing dies. To achieve the maximum potential use of carbide dies, press condition must be maintained at a high level. Although tool steel punches and dies can chip and shear because of misalignment, carbide punches and dies are more likely to break. Therefore, the presses used for tool steel dies can be in less than top-level condition and continue to produce quality laminations.

## Effect of Stock Thickness

Electrical sheet that is to be blanked and pierced usually ranges in thickness from 29 to 24 gage (0.343 to 0.607 mm, or 0.0135 to 0.0239 in.). Thinner or thicker stock is used for special applications. The blanking and piercing of extremely thin electrical sheet requires close control of equipment and technique. The processing of thick sheet (>1.27 mm, or 0.050 in.) can also cause difficulty, although the force-capacity rating of the press is the major factor that determines the maximum thickness of sheet that can be blanked and pierced.

Punch-to-die clearance for electrical sheet generally ranges from 3 to 7.5% of stock thickness per side, with clearances as large as 20% reported for grain-oriented stock. These values are similar to those used for low-carbon steel, but the stock thicknesses are thinner than those commonly used for the low-carbon steels. This results in close die clearance and requires good diemaking practice and accurate press equipment.

**Thin Sheet (≤0.254 mm, or 0.010 in.).** Under carefully controlled conditions, laminations can be blanked and pierced from sheet as thin as 0.051 mm (0.002 in.), but the press must be in top condition. Further, the feeding mechanism must be capable of feeding within ±0.076 mm (±0.003 in.) total error per stroke at a feed rate of 23 m/min (75 ft/min).

Punches and dies of hardened tool steel, such as D2, or carbide are satisfactory, although carbide dies and punches will have at least ten times the life of their tool steel counterparts. The punches must be rigidly supported and guided. The entire tool must be made rugged and accurate enough to maintain alignment. To avoid shearing the punch and die during press setup, it is important that the die be handled carefully to prevent the possibility of some of the components moving out of alignment. The press bed, the bottom of the die shoe, the face of the press slide, and the top of the punch holder must be clean and free of any irregularities that would cause a deviation from parallelism.

The punch and the die as a unit should be aligned square with the centerline of the press. The press slide should then be brought down slowly to meet with the top of the punch holder, and the punch holder should be fastened to the face of the slide. The slide should then be adjusted downward so that the punches enter the die cavities. Finally, the die shoe should be fastened to the bolster or press bed.

Dies with this close clearance are often designed as a unit, and the die is not fastened to the press ram. Therefore, the tool is not subject to the inaccuracies of the press.

A back taper of 0.002 mm/mm (0.002 in./in.) per side is commonly used in the die. Because of this angular clearance in the die, total die life is limited by the maximum punch-to-die clearance that can be tolerated. Each time a die having a back taper of 0.002 mm/mm (0.002 in./in.) per side is sharpened, the hole diameter will increase 0.1 μm (4 μin.) for each 0.0254 mm (0.001 in.) ground from the top of the die. After grinding 2.54 mm (0.100 in.) from the die, the punch-to-die clearance will increase 0.005 mm (0.0002 in.) per side.

If this amount of clearance is too great, the original clearance can be restored by installing new die sections or, if the dimensional tolerance permits, by using an oversize punch. The amount that can be removed from the die depends on the amount of back taper in the die, the stock thickness, and the maximum punch-to-die clearance permissible. Dies sometimes have a

Fig. 5 Small-diameter laminations produced in progressive dies. Dimensions given in inches

straight land that is 1.6 to 3.2 mm ( $1/16$  to  $1/8$  in.) wide before beginning the back taper.

Lubricant is applied to the stock during blanking and piercing to keep wear on the cutting edges of the punch and die at an acceptable level. Use of a water-thin lubricant with rapid evaporation and low residue makes it unnecessary to perform a burn-off operation before hydrogen annealing. Difficulties in producing acceptable laminations from thin sheet are magnified as the plan area of the lamination increases.

## Effect of Work Metal Composition and Condition on Blanking and Piercing

Each of the three most widely used electrical sheet materials (low-carbon steels and non-oriented and grain-oriented silicon steels) has distinctive punching characteristics. These characteristics often necessitate specific procedures to produce laminations of the desired quality at the lowest cost.

**Low-carbon steels** such as 1008 are used as electrical sheet when their electrical properties can meet requirements, primarily because they cost less than silicon steels and the cost is lower for blanking and piercing. More pieces per die sharpening are usually obtained in blanking these steels than in blanking silicon steels. One study of die wear in making stator and rotor laminations similar to those shown in Fig. 1 and ranging in diameter from 92 to 149 mm ( $35/8$  to  $57/8$  in.) showed that, with tool steel cutting edges, 120,000 to 150,000 pairs were punched per sharpening when stamping 1008.

The condition of the low-carbon steel stock influences power requirements and punching characteristics. When annealed, this steel has a tensile strength of 380 to 414 MPa (55 to 60 ksi), but the strength of full-hard material may be over 690 MPa (100 ksi). Therefore, the material condition must be known before the force-capacity requirements of the presses can be determined. Low-carbon low-silicon steels in the annealed condition are soft, and they are likely to roll at the edges and form excessive burrs. Therefore, punch-to-die clearances must be as close for these steels as for electrical sheet of the same thickness. An annealed product is usually specified, but whether annealed stock is stamped or individual laminations are annealed after stamping is often a matter of convenience, because of press capacity, annealing facilities, or other factors.

**Nonoriented silicon steels** are available with silicon contents ranging from 0.5 to 3.25%. As silicon content increases, the sheet becomes more brittle and more abrasive. As a result, the edges of higher-silicon steel are less likely to roll and make excessive burrs, but die wear is increased because of abrasion.

Many nonoriented silicon steels are coated with an organic or inorganic material (core

plating) to insulate one lamination from another. This organic core plating also improves the punchability of electrical sheet. In one application, carbide dies produced approximately 3.5 million laminations from core-plated M-36 (2.5% Si) between resharpenings. When similar laminations were produced from uncoated M-36, dies required sharpening after each 1.2 million parts. Heating of the coated blanks by welding or die casting may destroy the organic coating. Additional information is available in the section "Core Plating" in this article.

General practice is to use approximately the same punch-to-die clearances for all silicon steels. The tensile strength of the particular steel must be considered in determining press capacity because silicon steels may vary in strength, depending on whether they are fully annealed at the time of stamping.

**Oriented silicon steels** are relatively high in silicon (3.15% Si + Al) and have most of their grains (crystals) oriented with the cube edges parallel with the rolling direction and face diagonals at  $90^\circ$  to the rolling direction ( $\{110\}\langle 001 \rangle$ ). Because of this orientation, these steels have blanking and piercing characteristics that are different from those of nonoriented steels. Tensile strength will vary as much as 20% between the rolling direction and the transverse direction (strength is greater parallel with the rolling direction).

A magnesium hydroxide coating is applied to grain-oriented steel after normalizing. This coating prevents the coiled strip from welding together during annealing. Magnesium hydroxide, in contrast to the organic coatings, is highly abrasive and greatly increases die wear; therefore, it is not recommended for stamped laminations. Tool steel dies wear so rapidly under these conditions, because of the high silicon content of the steel, that carbide cutting edges are almost always used for the blanking and piercing of grain-oriented steel.

Because mechanical properties vary with direction, cutting properties also vary in grain-oriented steels. Cutting across the rolling direction results in a clean break, but the edges are smeared when cutting is parallel with the rolling direction. Therefore, punch-to-die clearance is more critical on the sides parallel with the rolling direction.

## Camber and Flatness

Camber in electrical sheet is the deviation (parallel to the stock surface) of a side edge from a straight line that extends to both ends of the side, and it is customarily limited to 6.4 mm ( $1/4$  in.) for any 2.5 m (96 in.) length or fraction thereof. Flatness, or the degree to which a surface of a flat product approaches a plane, is expressed in terms of the deviation from a plane. Flatness tolerances have not been established for electrical sheet; the operations employed to flatten other steel products cannot be used because of their effect on magnetic quality. Flatness

requirements should be specified for a particular application.

Camber and flatness are interrelated; the edge of a 2.5 m (8 ft) section of sheet may come within the 6.4 mm ( $1/4$  in.) tolerance while lying freely on a flat surface. However, the seemingly flat sheet may have a number of faint waves (sometimes called oil cans). If this sheet is then flattened (as it is in dies), the flattening of these waves causes multidirectional elongation of the sheet, and the edge of the sheet may then be forced into a camber different from that when the sheet is not under flattening pressure. Minimum camber and maximum flatness are desirable for blanking electrical sheet and are especially important in progressive-die operations.

**Effect on Progressive-Die Operation.** If there is no camber, it is easy to start the stock through the die correctly by aligning the straight edge of the sheet against a straight-edge starting guide, with the end of the material covering the first die stage. Feed rolls are then engaged, and the blanking and piercing can begin.

Even though the edge of the sheet is cambered, it must still be used in the starting alignment. Therefore, the material may be misaligned to some degree as it enters the die. A small degree of misalignment is not readily apparent to the press operator.

Minor misalignment in starting the material through a progressive die may not cause immediate problems. Operating difficulties result from various misalignments, which have a cumulative effect.

In the first stage of the die, pilot holes are pierced into the sheet, often into a portion that will later be scrap. At subsequent die stations, bullet-nose pilots engage the pilot holes as the die closes. The piloting action may cause the sheet to move slightly into true position before the cutting edges of the die meet the sheet. Powered feed rolls move the sheet between press strokes to an approximate position for the next die station. The feed rolls then open, releasing the sheet so that there is no conflict between the locating action of the pilots and the feed rolls.

When the original lineup is not correct or when there are cumulative effects of camber against the stock guides, the sheet may wander from side to side on the die face. Stock guides are provided in progressive dies to limit wandering due to camber and misalignment.

Interference between the pilots and the stock guides may cause the stock to distort and jam in the die, preventing proper flow of the stock. If the stock jams, the press must be stopped at once.

Camber can cause other difficulties. For example, a change in camber or multidirectional elongation of the sheet as the press flattens the waviness may cause the pilots to distort the piloting holes; thus, misaligned rotor and stator laminations are made. This leads to misalignment of the slots in the stacked core. As slots are blanked out, stresses are released that also can change the amount of camber and flatness.

There is no single solution to the problem of camber in the production of laminations in

progressive dies, because no two shipments of material are exactly alike. Some manufacturers of laminations use less efficient single-station dies because of difficulties with camber, even though production volume could justify the use of progressive dies. Other manufacturers use progressive dies only for laminations below a certain size.

## Burr Height

It is impossible to blank and pierce laminations without producing some burr along the cut edges (Fig. 6). The amount of burr (measured as burr height) depends on the composition and condition of the electrical sheet, the thickness of the sheet, the clearance between punch and die, and the edge condition (sharpness) of the punch and die.

The amount of burr that can be tolerated depends on end use. Burr height influences the stacking factor, which in turn influences magnetic characteristics. Maximum burr height is usually limited to 0.05 to 0.13 mm (0.002 and 0.005 in.).

**Length of Die Run.** A die is usually run until the maximum allowable burr height is reached, at which time the punch and die are removed for sharpening. Close control is required with this method of determining the length of the die run.

**Optimal Die Run.** For the greatest economy and convenience of operation, die maintenance requirements and die life (in addition to maximum burr height) should be considered in determining the optimal die run. A die should not be run too long before resharpening; otherwise, excessive stock must be removed from both the punch face and the die face to restore the cutting edges. As a result, fewer laminations can be made during the life of a die.

A common method of determining the optimal die run is to establish an arbitrary number of pieces to be run before die sharpening. At the end of this run, the punch face is sharpened. By

knowing the number of pieces run and the amount removed from the die during sharpening, the number of pieces produced per unit of length removed from the die can be established. Using this procedure, the number of pieces run between sharpenings can be varied, and an optimal die life between sharpenings can be determined.

## Lubrication

Although uncoated electrical sheet is sometimes blanked and pierced without lubrication, the use of some type of lubricant is preferred. Organic core plate (used on nonoriented silicon steels) serves as a lubricant, and no further lubrication is needed when blanking and piercing sheet that has core plating.

Tool life will be greatly improved by using a lubricant in the blanking and piercing of electrical sheet that has no coating or has been coated with magnesium hydroxide, which acts as an abrasive rather than a lubricant. Oil-type lubricants, such as those used in blanking and forming operations, are not ordinarily used for blanking and piercing electrical sheet, because removal is too expensive.

Some plants purchase nonoriented silicon steel sheet without core plate and then subject the punched laminations to an oxidizing anneal, in which the lubricant is burned off; the only requirement is to select a lubricant that will leave the least residue when it is burned off. Water-soluble oils (1 part oil to approximately 20 parts water) have been used when annealing follows punching. Other low-viscosity low-residue oils, such as the aliphatic petroleum, also burn off with little residue.

Liquid lubricants can be applied in several ways. In low-production operations, the work metal can be dipped into the lubricant just before punching. In high-production operations, in which the stock is continuously fed, the lubricant can be brushed on just before it enters the press, or it can be dripped onto the sheet a few feet from

the press. The top of the sheet is then rubbed with a felt wiper that spreads the lubricant over the entire surface. The bottom of the sheet can be coated with lubricant by having a trough under the sheet that catches the excess drip. A piece of felt or similar material in the trough acts as a wick to wet the underside of the moving sheet. A more complete discussion of lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

**Molybdenum disulfide** is a good lubricant for the blanking and piercing of electrical sheet. The amount used is usually so small that no removal is required. When there is an excess, it can be removed by immersing the sheet for 4 to 5 min in a dilute solution of stripper-type cleaner at 80 °C (180 °F).

Molybdenum disulfide is the basic ingredient of several compounds that are available as dry powder, paste concentrate, and dispersion in liquid. A common method of applying dry molybdenum disulfide is shown in Fig. 7. The sheet passes through a box containing the dry powder, and felt wipers remove the excess. A slurry can be used instead of the dry powder. Sheets can also be coated by a spray timed with the stroke of the press; either powder or a liquid suspension can be sprayed. In low-production operations, a liquid suspension of molybdenum disulfide can be applied to the sheet by brush.

## Core Plating

Core plating, or insulation, is a surface coating or treatment applied to electrical steel sheet to reduce interlaminar loss and sometimes to increase punchability. This treatment does not reduce eddy currents within the laminations. Interlamination resistance is usually improved by annealing the laminations under slightly oxidizing conditions and then core plating. Core plating can be classified as organic or inorganic.

**Organic insulation** generally consists of enamels or varnishes applied to the steel surface. Steels having organic coatings cannot be stress relieved without impairing the insulating value of the coating, but the coating will withstand normal operating temperatures. Coatings are approximately 0.0025 mm (0.0001 in.) thick.

**Inorganic insulation** usually includes chemical or thermal treatments; it has a high degree of electrical insulation and can withstand stress relieving. Inorganic coatings form a very thin surface layer on the steel and increase lamination thickness only slightly.

# Fine-Edge Blanking

T.C. Lee, C.Y. Tang, and L.C. Chan, The Hong Kong Polytechnic University

THE DEFINITION of fine-edge blanking, commonly known as fine-blanking, is very loose, but the most widely accepted description is that of the International Fine-Blanking Organization: "Fine-blanking is a hybrid metal forming process combining the technologies of stamping and cold extrusion. It produces a part with exceptional edge quality, superior flatness, thin wall sections, and linear spacing held to within 0.001."

Fine-blanking technology was invented by German engineer Scheiss in Switzerland in 1923. By 1959, the technology was being used in industrial applications. In subsequent years, the demand by the office-machinery industry for fine-blanked parts grew considerably. Then, in the 1970s, when office equipment became predominantly electronic, the fine-blanking industry experienced a major setback. This setback proved to be only temporary, however; increasing usage in automobile production and the

growing importance of this industrial sector have revitalized fine-blanking.

Initially, fine-blanking dealt mainly with materials 1 to 3 mm (0.04 to 0.12 in.) thick. The material types were limited to soft mild steel such as AISI 1006 (similar to GB St3 or EN 10027) or alloy steels such as AISI 5120 (similar to GB16MnCr5). Considerable technological breakthroughs in tooling and materials have advanced the technology and widened its application. It is now possible to make thicker parts in a variety of shapes and from a host of materials. Today (2006) more than 60% of fine-blanked parts (Fig. 1) are used in the automotive industry with thicknesses up to 19 mm (0.75 in.). Moreover, many alloy and carbon steels with good annealing properties are supplied for fine-blanking. Quality and cost are critical criteria when choosing a manufacturing method. As a cost-effective manufacturing technology, the

fine-blanking method has become a necessity in many major industrial sectors, replacing more expensive manufacturing options.

## Difference between Fine-Blanking and Conventional Blanking

In conventional blanking, a metal work-piece is removed from the primary metal strip when it is punched. A schematic diagram of the conventional blanking process is shown in Fig. 2.

A typical fine-blanking tool is a single-station compound tool used to produce a finished part in one press stroke. The only additional operation needed is the removal of a slight burr. The process requires a triple-action fine-blanking press that applies clamping force, blanking force, and counterforce to the fine-blanking tool,

**Fig. 2** Conventional blanking process. (a) Steel strip is fed into position when tool is open. (b) Guide plate holds the steel strip and punch drops. (c) Punch continues to pierce into the strip, and the part is blanked. (d) The strip is fed forward, ready for next cycle.

respectively. Figure 3 describes a typical single-station fine-blanking process. For more complex parts, multiple-station and progressive fine-blanking tools may be utilized.

Compared to conventional blanking, fine-blanking operations require more complicated presses (with three drive systems) that can produce high-quality products with good flatness and intricate shapes. Conventional machines are simple and require secondary operations. In conventional blanking, only a single force acts upon the material through the punch: the ram force. Fine-blanking makes use of multiple forces created by a blanking plate, a vee-ring, a punch, and an ejector. The ejector maintains pressure against the punch throughout the upward stroke. The three main forces in a fine-blanking cycle—clamping vee-ring force, an ejector/punch counterforce, and a blanking force—transfer through the vee-ring plate, ejector, blanking plate, and punch. At the onset of a typical fine-blanking cycle, a vee-ring force and an ejector counterforce act on the material. The vee-ring plate maintains a vee-ring force against the punch face. The two forces firmly clamp the material, inside and outside the periphery of the cutting edge, prior to shearing. The blanking

force, the third force in the fine-blanking cycle, occurs as the punch begins to cut. In a conventional blanking process, the punch tries to push the material through the die. However, the penetration is limited once the deformation exceeds the fracture strength of the material. The material in the clearance zone is subjected to tensile stretching, which, as it reaches the limits of the strength of the material, leads to fracture. The mechanical differences between the conventional blanking process and fine-blanking are listed in the Table 1 and illustrated in Fig. 4.

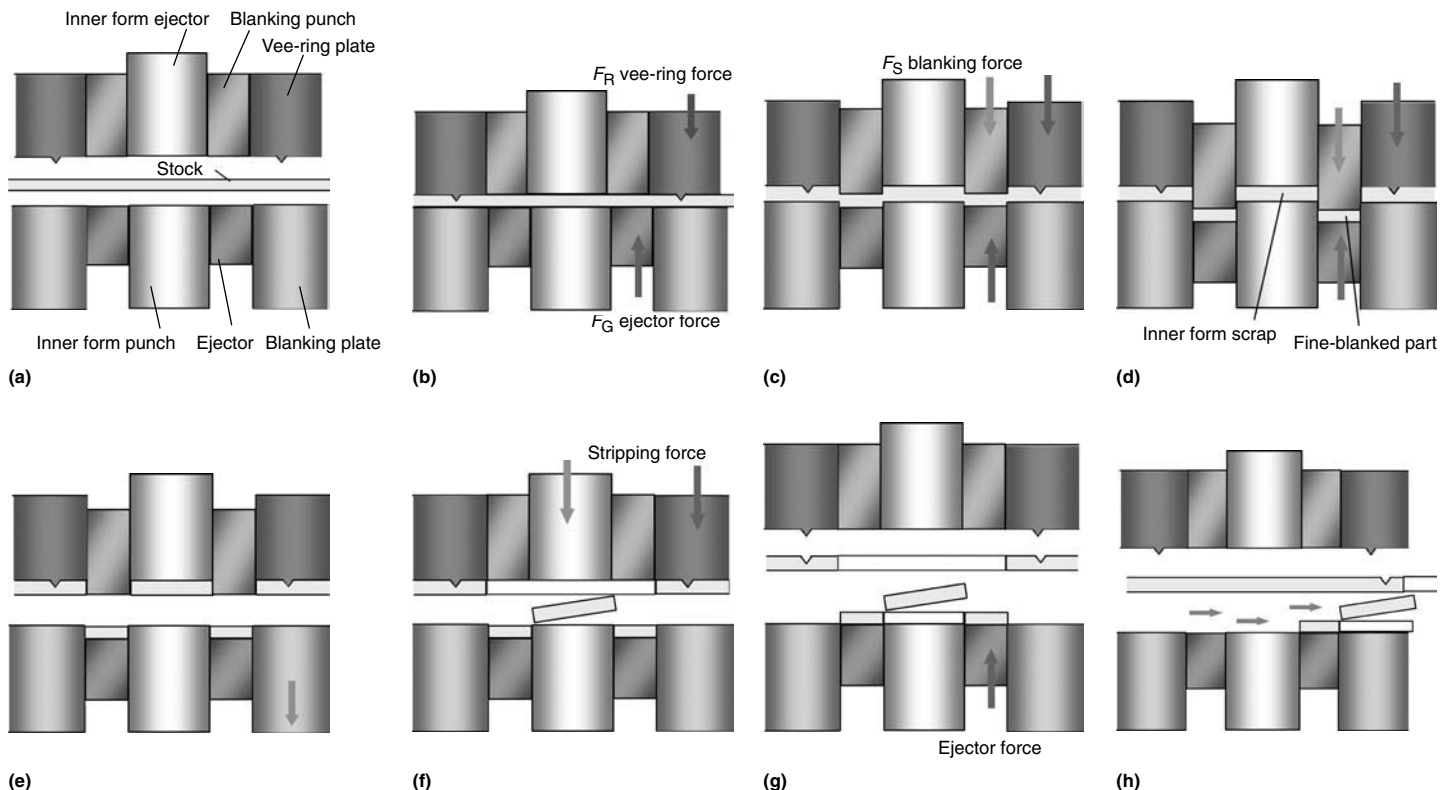

The distinguishing features of fine-blanking are the vee-ring, the small die clearance, and the counterforce loaded on the material. These generate compressive stresses, prevent horizontal movement of the material during the cycle, and stabilize tool elements.

### Design of the Fine-Blanking Process

The three principal design features of the fine-blanking process are the vee-ring, the clearance between punch and die, and the counterforce imposed by the ejector (Fig. 5).

**Vee-Ring Dimensions.** The vee-ring may be situated on both the guide plate and the die plate, or on only one of these. The dimension and position of the vee-ring depend on material thickness and surface flatness requirements (Fig. 6, 7 and Tables 2, 3). A vee-ring is used on both sides when the material thickness exceeds 4 mm (0.16 in.). Typically, the vee-ring contacts the material in an unbroken line all around the workpiece periphery. However, in special cases, an extra contact line that indents the scrap piece corresponding to the hole can be provided inside this periphery. In some cases, it may be advantageous to have a discontinuous vee-ring contact the periphery.

**Determination of Die Clearance.** In the fine-blanking process, the clearance should be kept at approximately 0.2 to 0.5% of the working material thickness, which is only one-tenth of that used in conventional blanking. A much smaller die clearance constrains the deformation within a narrow zone, which further restricts the flow of metal outside the deformation zone. Clearance is mainly determined by the material thickness (Fig. 8). However, it is also affected by punch profile and workpiece material.

**Fig. 3** A complete fine-blanking process. (a) Strip stock is fed into position when the tool is open. (b) Pressure is applied, closing the tool and embedding the vee-ring (also called stinger plate) into the stock. This prevents the material from flowing away from the punch, thus aiding in producing a smooth, extruded edge on the part. For thick parts, a vee-ring is also raised on the face of blanking plate. (c) The blanking force is applied to the stock by the ram, at the same time vee-ring constrains the movement of extra material. During this portion of the cycle, the counterpunch holds the part firmly against the face of the advancing blanking punch, maintaining flatness and preventing the part from moving away from the punch, which could cause die break or edge fracture. (d) The upward-moving ram advances the blanking punch until the part is fully sheared and rests in the upper die opening. In the same action, the punch pierces a hole in the workpiece. The scrap corresponding to the central hole is pushed by the counterforce inside the punch. (e) All three forces are relaxed, and tool starts to open. The ram descends by gravity. (f) The stripping force is 10 to 15% of the blanking force. This force acts to strip the skeleton from the blanking plate and eject the inner-shape scrap. (g) The ejector force pushes the finished fine-blanked part out of the die plate into the tool space. (h) The strip is fed forward, and the part and scrap are removed mechanically or by an air jet. The system is ready to start the next cycle.

**Force Calculation.** During a fine-blanking cycle, three forces act upon the material: the vee-ring force, the counterforce, and the blanking force (Table 4). The exact interactions among the three forces have a strong influence on the quality of the part and the performance of the fine-blanking process. Figure 9 and Table 4 show the empirical formulas used to calculate the forces.

Quality of the Cut Edge

A smoothly cut edge requiring no further machining is the most distinctive characteristic of the fine-blanking process. The quality of the cut edge depends on die clearance, lubrication, and blanking force. The cut edge is evaluated by several quality indices: dimensional tolerance, surface quality, and straightness or flatness of

the edge (Fig. 10). Dimensional tolerances that can be achieved in fine-blanked parts are listed in Tables 5(a) and (b). Cutting-edge quality consists of surface roughness, surface integrity, and allowable tearing level. The achievable surface roughness of a fine-blanked part is  $R_a$  3.6 to  $\sim 0.2 \mu\text{m}$ ; generally, surface roughness is  $R_a$  2.5 to  $\sim 0.63 \mu\text{m}$ . The surface integrity is indicated by the achievable smooth-cut section ratio, which is quantified with five levels (Table 6). The allowable tearing level is 4, according to experience in the fine-blanking field (Table 7).

Advantages and Limitations

As a high-precision manufacturing technology, fine-blanking has some advantages, not only in comparison with conventional stamping but relative to machining as well.

Table 1 Differences between conventional blanking and fine blanking

	Conventional blanking	Fine-blanking
No. of acting forces	One	Three
Force name	Major ram force	Major ram force Vee-ring force Counter force
Vee-ring	No	Yes
Die clearance	2–5% of material thickness	0.5–0.2% of material thickness
Secondary operation	Many operations are needed	Few or no operations are needed due to the high-quality surface

### Advantages

**Edge Quality.** The most obvious feature of a fine-blanked part is its completely smooth edge, which, if required, can be free of cracks and tearing. Conventionally stamped parts often have torn, rough, or tapered edges (Fig. 11). Commonly, the taper of the surface from top to bottom is less than  $1^\circ$  in a fine-blanking process and  $30^\circ$  in a conventionally stamped part. At the same time, due to work hardening, the sheared edges have an increased hardness, up to two times that of the base material.

**Flatness.** Throughout the fine-blanking process, pressure is constantly applied to both sides of the part, which achieves unmatched flatness. In general, fine-blanked part flatness can reach 0.025 mm per 25 mm (0.001 in. per 1 in.) of part length.

**Shape Complexity.** For a fine-blanked part, hole diameters as small as approximately 40 to 60% of material thickness and holes close

to the edge are possible with no loss in structural strength. Webs or slots with widths 60% of material thickness for steel, and 40% for aluminum and copper alloys, can be produced. In conventional stamping, approximately 150 to 200% of material thickness is required.

Finished gears can be fine-blanked with features broached and hobbled at the same time. Fine-blanking also can produce semipierced protrusions firmly affixed to the base metal, unlike conventional stamping, in which fracture occurs. Projections may also extend up to 100% of material thickness (Fig. 12).

**Table 4 Calculation of the required forces in a fine-blanking process**

Blanking force ( $F_S$ ), N $F_S = L \cdot s \cdot R_m \cdot f_1$	Vee-ring force ( $F_R$ ), N $F_R = L_R \cdot h \cdot R_m \cdot f_2$	Counterforce ( $F_G$ ), N $F_G = A_s \cdot q_G$

**Two-Dimensional Forming.** With the help of the three-drive systems of a fine-blanking press and progressive dies, products with bends and offsets to 70° can be achieved in a single fine-blanking cycle. The maximum offset distance can be four times the sheet thickness (Fig. 13). A complex shape product (Fig. 14) can be finished in one station, saving a considerable amount of time.

**Cost Effectiveness.** With fine-blanking, the part is produced to net shape without extensive poststamping machining. Costly machining, such as shaving, milling, reaming, or grinding, is not needed to eliminate die break. The clean edges meet the high standards for parts requiring full bearing or sealing contact on sidewalls or smooth edges for cosmetic reasons. Additionally, small holes and thin web sections can

**Fig. 11** Edge quality comparison. Top: Fine-blanking: Full shear, 50 RMS; less than 1° taper. Bottom: Conventional stamping: up to 80% die break; taper as great as 30°

**Fig. 12** Complex shapes achieved by the fine-blanking process

**Fig. 13** Two-dimensional forming

**Fig. 14** A sample two-dimensional part made by fine-blanking

be produced in one stroke of the fine-blanking process; thus, costly secondary drilling and machining operations are unnecessary. Finished parts keep a high tolerance from part to part within a production lot and from the first production lot to the last.

When compared to conventional stamping, the main drawback of the fine-blanking process is the high price of the press system, often several times higher than a conventional system. Generally, if a part can be made to specification by conventional stamping, it will cost somewhat less than if made using the fine-blanking process. However, fine-blanking can eliminate the need for secondary operations in a stamped component and meet dimensional requirements that conventional stamping cannot match.

### Limitations

**Die Roll and Burr.** Two common features, die roll and burr, exist in blanked parts. However, these defects exist to a lesser degree in fine-blanked parts. Die roll is greater on corners than on straight edges and, in general, the harder or thinner the material, the smaller the die roll. The amount of die roll depends primarily on the geometric form, the corner angles, and the radii (Fig. 15). Moreover, as a rule of thumb, the width  $a$  of the die roll is usually about 5 times its height  $b$ .

Burr, located on the side opposite the die roll, is another inherent feature of a fine-blanked part. Die roll and burr size depend on the part material, blade sharpness, the extent of wear of the die, and the shape of the part. The size of the die roll and burr tend to increase with the number of parts produced, reflecting gradual wear on the tool.

### Working Material

Any material suitable for cold forming can be fine-edge blanked, including low- and medium-carbon steels, some alloy and stainless steels, copper and brass, and aluminum alloys. Table 8 (Ref 5) lists typical conditions of fine-blanked materials. Table 9 lists in more

**Fig. 15** Die roll and burr in fine-blanked parts.  $R$ , corner radius;  $\alpha$ , corner angle;  $a$ , die roll width;  $b$ , die roll height;  $c$ , burr height;  $d$ , burr width;  $S$ , material thickness. Source: Ref 3

**Table 8 Materials for fine-edge blanking**

Material	Condition
<b>Carbon steels</b>	
1008–1024	Up to fully hard
1025–1095	Spheroidize annealed
<b>Alloy steels</b>	
AISI 4000 series, 8000 series	Spheroidize annealed
<b>Stainless steels</b>	
AISI types 301, 302, 303, 304, 316, 430, 416	Fully annealed; shorter tool life than for plain carbon steels
<b>Aluminum alloys</b>	
1xxx, 3xxx, 5xxx series	H (strain hardened) temper; O (annealed) temper
6061, 7075	T3 or T4 for thinner gages
<b>Copper alloys</b>	
C26000 (cartridge brass, 70%), C26800 (yellow brass, 66%)	Annealed, quarter hard, or half hard
C27400 (yellow brass, 63%)	Fully hard in thin gages
C17xxx (beryllium copper alloys)	Annealed only
<b>Other nonferrous metals and alloys</b>	
Monel alloy 400	Annealed
Soft bronzes	Annealed
Silver, gold	Excellent results

400	58	15.0	0.590

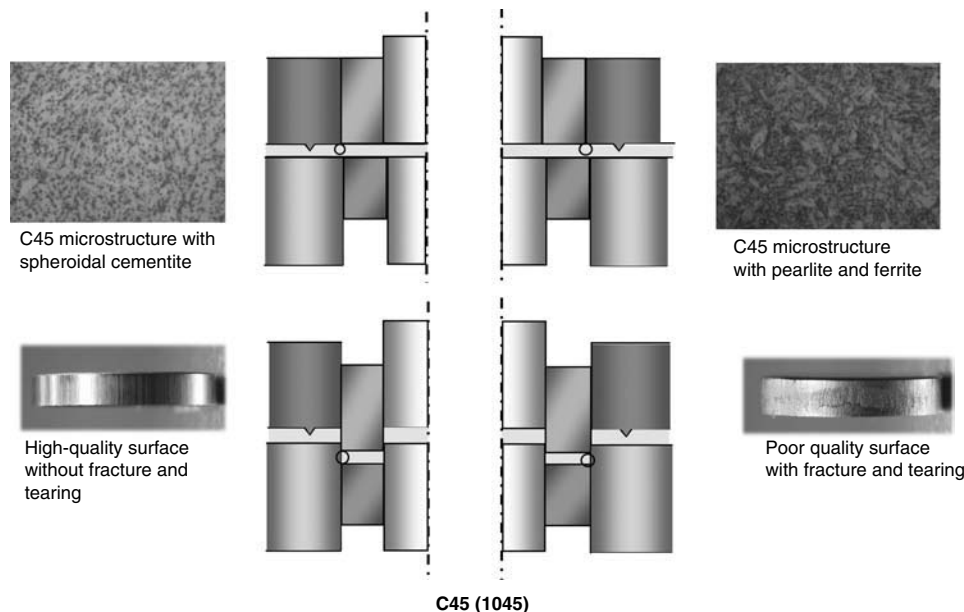

detail suitability of material conditions for fine-blanking.

The mechanical properties of the work material have a direct influence on surface quality, dimensional tolerances of the fine-blanked part, and tool life. The basic requirements of the material are:

- **Good ductility.** The better the ductility, the higher the deformation capacity. The material in the deformation area flows without fracture as the punch moves.
- **Low yield strength.** Low yield strength and tensile strength help to create good lubricating condition, improve the quality of sheared edge, and increase tool life. The allowable thickness of the work material is primarily governed by its strength. Material less than 15 mm thick can be fine blanked. However, work material thickness is usually in the range of 2 to 4 mm (0.08 to 0.16 in.) (Table 10).
- **Homogeneity.** Fine-blanking requires a fine microstructure because different heat treatments result in different microstructures and plasticity which, in turn, affect the quality

**Table 9 Types of materials suitable for the fine-blanking process**

Material	Most	Degree of suitability		Least
<b>Carbon steel</b>				
Low carbon (C1006–C1020)	45–75 HRB, T No. 3 No. 5 (quarter- hard and dead-soft)	70–85 HRB, T No. 2 (half-hard)	84–90 HRB, T No. 1 (full-hard) (thin)	T No. 1 (full-hard) (heavier gage)

**C45 (1045)****Fig. 16** Comparison of suitable and unsuitable 1045 steel microstructure for fine-blanking and the resulting blanked edges. Source: Ref 1

of the fine-blanked part. For carbon steel and alloy steel, the shape and distribution of carbides are critical to the fine-blanking process. Material with perfect spheroidization, even distribution, and good dispersion of fine carbides is most suitable for the fine-blanking process.

The example in Fig. 16 provides various results obtained using the same material but with different microstructures. The material on the left in Fig. 16 with a fine microstructure comprising a ferrite matrix with spheroidal cementite is suitable for fine-blanking. During the fine-blanking process, instead of separation

from the matrix, the spheroidal cementite grains are pressed into the soft ferrite matrix, which results in a flat, smooth surface. On the other hand, the material on the right displays an unsuitable microstructure composed of ferrite and pearlite. The hard cementite plates have to be broken when the blanking punch penetrates the material. The result is die fracture.

In addition to material properties, the geometric configuration and the thickness are the prime factors determining the applicability of the fine-blanking process. In order to determine if a part is suitable for fine-blanking, its degree of difficulty must be assessed: S1 (easy), S2 (medium), and S3 (difficult). To gage the feasibility of the fine-blanking process, the various formed elements, such as slot widths, section widths, hole diameters, tooth forms, corner angles, and radii can be evaluated with the help of Fig. 17.

**Carbon and Alloy Steels.** The easiest materials to fine-edge blank are low-carbon steels (less than approximately 0.25% C). Thin parts, however, have been fine-edge blanked from plain carbon steels containing up to about 0.95% only in the fully annealed, spheroidized condition (Table 8).

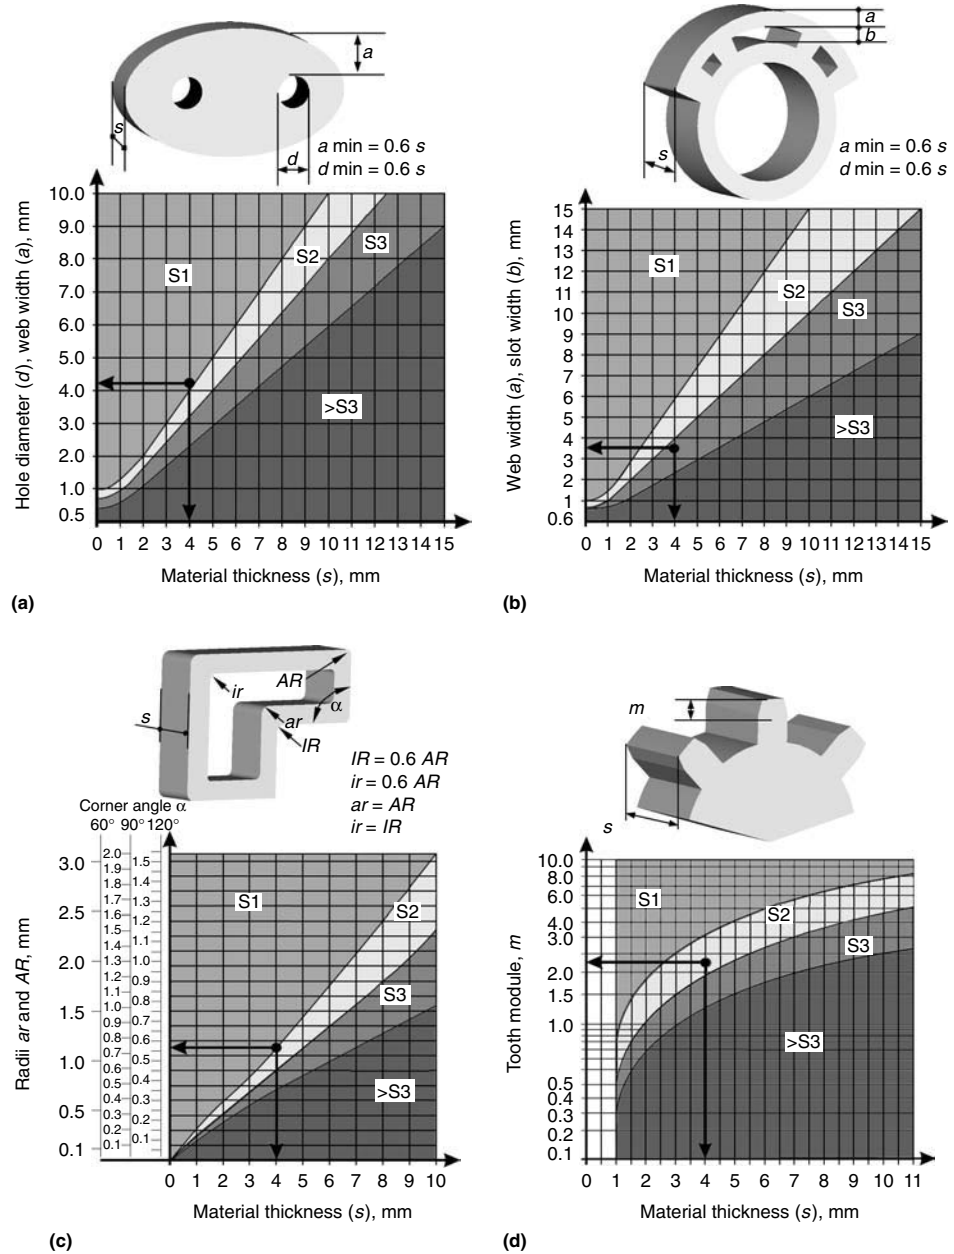

**Stainless Steels.** Austenitic stainless steels, such as AISI types 301 to 304 and 316, can be fine-edge blanked in the fully annealed condition. These materials, as well as the ferritic type 430 and martensitic type 416 (both fully annealed), have good blanked edges, but cause higher tool wear than do plain carbon steels.

**Most aluminum alloys,** with the exception of alloy 2024, can be fine-edge blanked in the O (annealed) temper. Wrought alloys of the 1xxx, 3xxx, and 5xxx series can be fine-edge blanked in the H (strain hardened) temper with excellent results. In thinner gages, alloys 6061 and 7075 can be fine-edge blanked in the T3 or T4 condition.

**Copper alloys** are easily fine-edge blanked. The most workable alloys, such as alloy C27400 (yellow brass, 63%) can be fine-edge blanked even in the full hard condition. Other brasses, such as C26000 (cartridge brass, 70%) and C26800 (yellow brass, 66%) can be worked in the annealed, quarter-hard, or half-hard condition. Beryllium-copper alloys can be fine-edge blanked in the annealed condition, as can pure copper, soft bronzes, Monel alloys, nickel-silvers, and silver and gold.

nected to the press via the punch base (1), runs in the guide plate or vee-ring plate (19) in the lower die set (2). In the upper die set (7), the blanking die plate (16) is mounted and additionally sup-

ported by the base plate (15), piercing punch retaining plate (9), backup plate (10), and supporting plate (12). The ejector (18) is guided into the blanking die plate. The ejector in turn guides

## Fine-Blanking Tooling and Lubrication

**Types of Dies.** Fine-blanking dies are usually classified into “moving punch” and “fixed-punch” systems. The moving-punch system (Fig. 18) is used mainly for the production of small to medium-size parts with few inner forms and, in most cases, on mechanical fine-blanking presses. This tooling system is very compact and economical to make and use. In this moving-punch tool, the moving punch (5) which is con-

Different features	Symbol meaning	Requirement

s, work material thickness. Source: Ref 1, 3

**Fig. 17** Difficulty ratings of various features used to evaluate the overall difficulty rating for a part. S1, least difficult; S3, most difficult

the inner forming punch (14). Via the pressure pins (11) and the pressure pad (13), the counterpressure, that is, the ejection force, is applied to the ejector (18). The inner form slugs are ejected by the press hydraulic system via the pressure pins (20) of the ejector bridge (3), and

the inner forming ejector pin (4) is ejected from the punch (5).

For most fine-blanking work, a fixed-punch system (Fig. 19) is preferred and it is suitable for all die types, in particular for the manufacture of thick, large parts. The blanking punch (14) is

positioned on a hardened pressure plate (8) on the upper die set (7), where it is permanently positioned and fastened. The precisely fitted guide plate (6) and the vee-ring plate (17), which bear the latch bolts (15), guarantee the fitting precision of the blanking punch (14) relative

Fig. 18 Moving punch system

Fig. 19 Fixed-punch system

to the blanking die plate (18) by means of the column gib unit (16) of the frame. The inner form slugs are stripped from the blanking punch (14) by the inner forming ejectors (9) and (13). Pressure is applied on the ejectors (9) and (13) and the vee-ring plate (17) by the vee-ring piston of the press via the pressure pins (11) and (12). The pressure pins (11) transmit the force of the vee-ring during the blanking process and the stripping force during the stripping cycle. The blanking die plate (18) is located, positioned, and fastened on the lower die set (2). The ejector (5), which is guided in the blanking die plate (18), also guides the inner forming punches (19) and (4) and transmits the counterpressure and ejection force from the counterpressure piston of the press via the pressure pins (21). The inner form punches (19) are mounted on the piercing punch retaining plate (20) and supported by the backup plate (1).

Like all conventional stamping tools, both fixed and moving punch systems can be extended to progressive blanking dies, compound progressive dies, and transfer dies (Fig. 20). With progressive and compound dies, an additional coil material guidance system (5), an initial blanking stop (13), pilot pins (21, 14), and positive press-off pins (16) are required. The coil guide ensures not only coil guidance but also stripping of the scrap web from the pilot pins (21, 14). The initial blanking stop (13) ensures precise initial blanking of the sheet metal at the beginning of a coil or strip. The pilot pins (21, 14) position the sheet metal precisely in each die station; that is, they ensure that the prescribed feed step is adhered to precisely. The positive press-off pins (16) compensate for

the counterpressure so that it does not have to be absorbed fully by the individual piercing punches (12) during initial blanking in the first die station.

**Tool Material Requirements.** The demands placed on the tool materials in service increase in direct proportion to sheet metal thickness and the strength of the workpiece material. If the active elements of the tooling, that is, the punch, undergo severe cyclic impact, they will quickly be destroyed. The challenge posed to the manufacturer of tool materials for fine-blanking is the need to produce tooling grades with better plastic deformation resistance and wear resistance while maintaining toughness. Table 11 gives the tool materials most commonly used today (2006). Most of these are high-speed steels, some of which meet the various requirements of die and periphery components (Table 12). Some tool steel manufacturers have developed a powder metallurgy production technique to increase both plastic deformation resistance and wear resistance, as well as to increase the toughness of fine-blanking tools.

**Heat Treatment of Tooling.** Proper heat treatment is also one of the critical factors for controlling tool performance. The tool properties, including hardness, toughness, compressive yield strength, and dimensional stability, are affected by heat treatment. The two key components of the heat treatment cycle are the quenching rate and the choice of tempering temperature. The minimum quenching rate for a given tooling grade is set by its continuous-cooling-transformation diagram. The ideal cooling rate is sufficient to achieve a fully martensitic microstructure while avoiding the

formation of bainite. Furthermore, pearlite formation should be prevented in all cases, as it is very detrimental to the toughness of a tool. For high-alloy cold-work tool steel grades, minimum quenching rates in excess of 20 °C/min (35 °F/min) are often recommended.

The other crucial aspect of heat treatment is the selection of tempering temperature. Generally, three tempering temperature ranges are available for a specific cold-work grade: low range (approximately 400 to 600 °F, or 200 to 315 °C), intermediate, and high tempering range (980 °F, or 525 °C, and above). The intermediate range is not recommended because tool toughness is severely degraded in this range. The low tempering temperature range yields the best toughness properties for the grade at the selected working hardness. The high range is a sound choice for fine-blanking tooling, although the toughness properties obtained are not as good as those achieved using the low tempering range. With high-temperature tempering, for a high-alloy cold-work grade, some retained austenite transforms to the hardened martensitic structure.

**Carbon Steel Performance for Tooling Component.** Carbon steel is widely applied because it is inexpensive, possesses high hardness after heat treatment, and can easily be cold worked or hot worked. This material, however, is not without its disadvantages: narrow quenching temperature, poor hot hardness, low wear resistance, and brittleness after the quenching process. Carbon steels are used to produce less critical parts, such as the ejector rod and locator pin. The most commonly used type is AISI W1 (T72301, or GB T8A, T10A). Special forging

processes may be used to improve the performance of these materials:

- Heating: 1100 °C (2010 °F)
- Heating duration: approximately 1 to 1.5 min/mm (0.04 to 0.05 min/in.)
- Original forging temperature: approximately 1000 to 1050 °C (1830 to 1920 °F)
- Finished forging temperature: approximately 800 to 850 °C (1470 to 1560 °F)
- Cooling method: air cool

**Coatings.** Surface treatment is another method used to prolong tool life and increase product dimensional accuracy. Physical vapor deposition (PVD) and chemical vapor deposition (CVD) are two major methods applied to tools and machine elements to improve corrosion, friction, and wear properties. There are four commonly used coating types, titanium nitride (TiN), titanium carbon nitride (TiCN), titanium aluminum nitride (TiAlN), and chromium nitride (CrN), whose properties are listed in Table 13. Fine-blanking tools with PVD/CVD coatings have a longer tool life, ten times greater wear resistance, and high surface smoothness. Examples of coated fine-blanking tooling are shown in Fig. 21.

**Lubrication** is important in fine-blanking. Without it, the process would lead to cold welding of the active elements (i.e., punch, die) to the blank and rapid wear and blunting of the die. Accordingly, precautions must be taken to ensure that the active elements are supplied with sufficient lubricant at every point of the cutting edge and forming areas in the die. The application of fine-blanking oil to the sheet material can be carried out by using rollers or spray jets. In order to have both the top and the bottom surfaces of the sheet metal evenly wet by a film of lubricant, some wetting substances are added to fine-blanking oils. When a spray system is used, oil mist must be removed using a suitable extraction device. If high-viscosity oils are used for thick, higher-strength materials, it is also possible to apply lubricant through rollers. In order to ensure that the fine-blanking oil applied to the sheet metal surface also reaches the friction pair during the blanking process, parts of the die must be tailor-made to create some lubrication pockets along the cutting edges (Fig. 22).

**Fig. 21** Examples of coated fine-blanking tooling**Fig. 22** Formation of the lubricant film in the die

The fine-blanking oil must be capable of withstanding different levels of stress and temperature to the extent that the lubricant film remains intact during the blanking process. No one type of lubricant can satisfy multiple fine-blanking applications. The fine-blanking oil used in each case must be specially adjusted according to the work material, the thickness, and the strength of the part. The viscosity of the oil must match the specific types of stress occurring during fine-blanking. Typical lubricants are listed in Table 14.

## Fine-Blanking Press

The fine-blanking process requires a controlled sequence of movements with a precise top dead center. The strict blanking clearance of the dies must not change, even under high

levels of stress. Fine-blanking presses, therefore, must meet the stringent precision requirements, including slide gibs, high frame rigidity, and parallelism of die clamping surfaces. Both mechanical and hydraulic systems are used for the main slide drive.

The mechanical fine-blanking press (Fig. 23, 24) is notable for its sturdiness and operational reliability under the tough conditions of daily use. It is equipped with a "combination bed" for the tool system with moving and fixed punches (Fig. 18, 19). Making use of the straight-side principle, the monoblock press frame as a welded construction offers good dimensional rigidity and avoids vibrations. A clearance-free pretensioned slide gib is used. A central support in the upper and lower die clamping plate ensures optimum die support and introduction of force to the die. A controlled, infinitely variable direct-current (d.c.) motor drives the press via the flywheel, consisting of a disk clutch and a worm gear pair on two synchronously running crankshafts of different eccentricities.

The crankshafts drive a double knuckle-joint system that generates the movement sequence of the slide required for fine-blanking. This drive system is particularly well suited for material thicknesses between approximately 1 and 8 mm (0.04 and 0.3 in.) and total press forces up to 2500 kN. The vee-ring force and counterforce are applied by hydraulic systems. The mechanical drive system has:

- A fixed slide-movement sequence with constant stroke and precise position of the top and bottom dead center

- Low energy consumption
- High output (depending on the size of the press) with stroking rates of up to 140/min
- Minimal setting and maintenance input

The high manufacturing precision of fine-blanked parts and the tight clearance of the process demand a rigid press frame and precise ram guidance. In the example below for a mechanical fine-blanking press, ram movement is broken down into four stages: (a) rapid closing, (b) sensing movement and engagement of vee-ring, (c) cutting movement, and (d) rapid opening. During the cutting stage, the travel speed is as slow and as constant as possible, whereas the no-load strokes (a) and (d) are as rapid as possible (Fig. 25).

Figure 26 shows a schematic and photograph of a hydraulic fine-blanking press. Most efficient hydraulic fine-blanking presses with a total force ranging between 2,500 and 14,000 kN are equipped with a pressure accumulator drive. In this kind of press, the body frame is made of a robust welded monoblock straight-side construction with high rigidity. This is achieved by designing large upright cross sections and large ribs. The slide and main pistons together form a unit that is integrated in the press bed. The counterpressure piston is integrated in the slide, and the vee-ring piston is mounted in the press crown. Both pistons are equipped with support bolts to provide support over the entire surface of the dies. The slide is guided in the press body and the gib is a high-precision, multitrack sliding gib. This construction alleviates slide tilting, even under major eccentric loads.

According to the fine-blanking press manufacturer, a hydraulic fine-blanking press has:

- An integrated tool-breakage safety system independent of the tool itself
- All regulation safety systems for personnel protection
- A high degree of operational reliability in the work process

**Table 14 Lubricants used in the fine-blanking processes**

	Composition	Percentage, %
F-1 lubricant	Chloride paraffin	10–15
	Organic acid ester	0.1–1
	S · P additive	5–10
	50# machine oil	75 to ~85

	Mineral oil	16
	Glycerine	7
	Castor-oil oleate	4
	S · P barium additive	7

**Fig. 23** Mechanical fine-blanking press

## Alternative Tooling and Equipment

Several alternative approaches have been developed for fine blanking. A schematic diagram of a typical hydraulic-tooling die system is shown in Fig. 27. It is composed of a lower and upper die-set bolster, lower and upper piston, lower and upper base plate, gib system, and spring. High precision is guaranteed by the four rigid columns of the gib system. The hydraulic cylinders and pistons provide vee-ring force and counterbalancing force when the die is closing, and unloading force and stripping force when the die rebounds after the oil reservoir in the die bolster is filled with hydraulic fluid.

A conventional hydraulic press system may combine the fine-blanking function with the

n addition of a hydraulic tooling-die system. The installation and disassembly is the same as the normal die set without the additional refit to

the press. The press can be used for conventional blanking processes when the hydraulic die-set system is removed.

## Application and Development in the Future

### Current Applications in the Industry.

Fine blanking is used not only in the mass-production of precision parts, but also in the batch production of intricate parts. Fine-blanked parts are currently found in many different products, such as automobiles (Fig. 28), airplanes, and office machines. Recent advances in this process have particularly attracted the automotive industry, with its high unit quantities and need to remain competitive.

The bicycle and motorcycle industries have also introduced many fine-blanked parts such as gears, gear levers, gear cams, and cam plates. Chain sprockets and the rotors of centrifugal clutches include a number of fine-blanked parts. Even the perforated disk brake on high-performance motorcycles (Fig. 29) are now made by fine-blanking.

Advances in electronics have virtually eliminated the need for many mechanical control and transmission systems and thus reduced such applications of fine-blanking. However, the electronics and computer sectors, with their high precision requirements and new materials, have created new applications for the process such as computer hard-drive components (Fig. 30). Another important application of fine-blanking is the manufacture of blades, cutlery, hand tools, and surgical instruments.

The potential of the process to manufacture less expensive and better quality parts has not been exhausted. Many new applications in the automotive, electronics, and appliance industries are constantly emerging. By combining cold forming with fine blanking, creative design solutions involving bending, countersinking, semipiercing, coining, cranking, or deep-drawing become possible. In the vast majority of cases, new applications are no longer of simple flat parts, but components in which fine-blanking is used in combination with other technologies (Fig. 31).

**Future Trends.** With the rapid development of advanced, low-cost computers, the finite-element method (FEM) can be now widely applied for the numerical simulation of sheet-metal forming processes, including the fine-blanking process. With the proper material properties and simplified boundary conditions, FEM can predict the pertinent stress conditions through the whole blanking area to investigate process mechanics. Also, with numerical simulation, working parameters can be optimized without expensive shop trials.

Typically, most engineers use computer-aided design (CAD) programs to create tools with the same geometry as those used in the process simulation or virtual manufacturing. Manufacturers can simulate their production process in a virtual environment to save time and money spent on real pilot production or practical tests at the verification stage. In addition, simulation results provide useful information to

# Presses and Auxiliary Equipment for Forming of Sheet Metal

STAMPING PRESSES are built with meticulous attention to accuracy, clearances, parallelism, deflections, and controls. With the use of precision die-making machines and the use of better-grade die materials, precision presses are needed for satisfactory operation in achieving the long life and extremely close clearances of expensive dies. Intricate dies require presses that run with better guiding and deflection characteristics. One example of this tooling is the progressive die, which combines many operations in one press to produce a finished part with each stroke. This tooling, coupled with automatic feeding and ejection equipment, leads to greater press speeds for more production at less cost per piece.

This article describes various types of press construction and the factors that influence the selection of mechanically or hydraulically

powered machines for producing parts from sheet metal. A press (Fig. 1) can represent a substantial capital investment, and proper selection of a press is essential for successful and economical operation. No general-purpose press exists that can provide maximum productivity and economy for all applications. Compromises usually must be made to permit a press to be employed for more different jobs or flexibility for future production requirements.

## Types of Presses

There are three basic components in a press: the frame, the drive, and the gibbing. Presses are broadly classified, according to the type of frame used in their construction, into two main groups: gap-frame presses and straight-side presses. Details of construction vary widely in each group, but typical examples are illustrated in Fig. 2 and 3 for a straight-side press and an open-back inclinable (OBI) gap-frame press, respectively. Power presses also can be classified further according to the source of power (mechanical or hydraulic), method of actuation of slides, and the number of slides in action. Presses in any of these classes are available in a

range of capacities (tonnage or bed area), although the range is not necessarily the same for all types of presses. Characteristics of 18 types of presses are summarized in Table 1.

**The Joint Industry Conference (JIC)**, a committee of press builders and large-press users formed some years ago, set guidelines for uniformity with respect to nomenclature, bed and ram sizes, force ranges, and symbols for presses. Although JIC is no longer in existence, most press builders adhere to the standards either completely or in part. Under the JIC press classification system with respect to the number of slides, the first letter in the designation is *S* for single-action, *D* for double-action, and *T* for triple-action presses. Other designations used for visible identification of presses suggested under the JIC classification system are given in Fig. 4. Most press builders place these markings in a prominent position on the fronts of the presses.

**Source of Power.** Power presses can have mechanical or hydraulic drives with principal components (Fig. 5, 6). The performance characteristics and other operational features of hydraulic and mechanical presses are compared in Table 2. Mechanical presses are frequently used, but hydraulic presses are being increasingly

Fig. 1 Stamping press

Fig. 2 Typical straight-side press frame

applied. There are applications for which hydraulic presses offer certain advantages and, in some cases, are the only machines that can be used. For example, very high force requirements can be met only with hydraulic presses.

In some respects, the gap between the advantages of selecting a mechanical press over a hydraulic press and vice versa has narrowed due to improvements in design and the addition of features to each type that duplicate the desired actions of the other. An example would be mechanical presses with varidraw drives to improve speed during drawing operations. Hydraulic presses were once the only presses considered for deep draw work, while mechan-

ical presses were used for blanking, forming, and shallow draws. The speed of the press is determined by the speed at which a material can be drawn because the material may tear if the speed is exceeded. In the case of the mechanical press, this then determines the speed of the press through its entire cycle, which is generally slower than the full speed capability of a mechanical press. By installing a varidraw drive, a slower speed can be maintained at the recommended drawing speeds only for that portion of the stroke cycle where the draw occurs, while increasing the speed of the press through the balance of the cycle. Varidraw drives on mechanical presses can as much as double

the production of the press in drawing operations.

Another important advantage of hydraulic presses over mechanical presses has been the fact that a hydraulic press cannot be overloaded. This advantage has been eliminated by the introduction of overload units that can be installed in mechanical presses. These units basically consist of a hydraulic cylinder, installed within the connections of the press that maintains a constant and adjustable pressure that, when exceeded, causes the cylinder to collapse and stop the press, preventing any damage to the press proper. After the obstruction (the cause of the overload) has been removed and the overload reset, the unit will automatically build up to the predetermined pressure and be ready to resume its function.

The choice today of a mechanical or hydraulic press becomes more a question of production requirements, economics, versatility, and the type of work to be performed within the press. Hydraulic and mechanical presses can be single-action or double-action, as described in the section "Number of Slides" in this article. Advantages and disadvantages of each are described in the section "Press Selection" in this article.

## Press Frames

The basic job of the press frame is to contain the load and control the deflection. It follows directly that the bed and slide members of the press, onto which the die shoes are fastened, must exhibit a similar degree of rigidity to back

Fig. 3 Typical gap press frame (open-back inclinable)

up the die shoes when under load. If the press members deflect excessively under full load, the die shoes will also deflect, following to some degree the deflection of the press members. When this occurs, both upper and lower die elements are distorted. As a result, the finished stamping may not come up to full expectations because the center of the die has been deflected away from its normal position.

Steel and cast iron are two basic types of materials used in the construction of press frames. The stress design factor used by reputable builders is conservative, and consequently there does not appear to be much difference in the deflection of the component parts, whether they are made of steel or of cast iron. However, one of the big advantages of steel is the straight-line relationship to the yield point (Fig. 7). This provides a big safety factor in the event that the machine is overloaded. Another advantage of steel is that it is basically easier to repair than cast iron. The steel plate used in presses comes as a homogeneous rolled plate, which eliminates the possibility of internal discontinuities such as blowholes and slag inclusions sometimes found in cast frames. Steel fabrications also lend themselves to the utilization of uniform cross sections, which reduces the extent of stress-concentration regions that might lead to trouble later on.

Basic engineering sections can be used in the design of fabricated presses, which allow the use of standard formulae with empirical relations that closely resemble the actual deflection characteristics of the frame. This, of course, is an important point when designing a press for the very-low-deflection characteristics required in many cases with carbide-type tooling. Generally speaking, however, fabricated steel machines do not weigh as much as cast iron machines because with fabricated steel, we can take advantage of standard structural shapes to provide rigidity where it is required. It is not necessary to have the excessive mass found in a cast iron structure.

Fabrication has become increasingly common in recent years, and most press builders will quote on fabricated machines. It is extremely important, however, that the large weldments, which form the basic component of the frame, be thoroughly stress relieved. Also important in conjunction with stress relieving is to have the frame grit blasted to remove objectionable scale and provide a good base for primer paint.

**Gap-frame presses** (Fig. 8) are sometimes called C-frame presses because the frame resembles the letter C when viewed from the side. Their most distinguishing feature is unobstructed die space accessible from all sides except the rear. In some cases, even the rear is

accessible. Because of their extreme versatility, gap-frame presses are used for a great variety of operations such as piercing, blanking, and drawing.

Gap-frame presses feature versatility of application and material handling. The gap makes the die area accessible from either side, as well as from the front, for ease in die setting or for feeding stock. Coil stock often is supplied to gap-frame presses by feeders from stock reels and straighteners. Workpieces usually are ejected through an opening in the press bed, or through the back of an open-back press. (A few gap-frame presses with solid backs are in service, but solid-back presses are coming into increasing disfavor because work cannot be ejected through the back of the press and because the design in general is less convenient than is the open-back type.)

Gap-frame construction has one disadvantage: As the load is imposed, the mouth of the C will have a tendency to "alligator," or open, thus causing angular deflection. (A straight, vertical deflection would be less critical.) Gap deflection resulting from overload causes misalignment of punches and dies, which is a major cause of premature die wear.

Figure 9, which shows a typical right-to-left shaft-inclinable press frame, indicates some significant structural points. Combined bending and direct stress loads are encountered in both the upper and lower cantilever beams (C-C and B-B). These loads extend forward the distance D to support, respectively, the main bearing structure above and the press bed below. It is noteworthy that the upper cantilever beam has a section C-C, which is very deep in relation to the throat, D. Therefore, deflection in this upper cantilever beam is so small that it can be neglected in calculations.

Standard gap-frame presses are built with one-piece frames. Designing these presses with the proper rigidity is, therefore, considerably more complex than for presses with straight-side frames. The total deflection of the gap area is made up of both vertical and angular deflection and is a function of gap height and depth. The angular deflection is the more important of the two as far as the press user is concerned because it may result in misalignment between punch and die.

When a gap-frame press is fabricated from steel plate, the side plates that form the uprights of the frame have a uniform cross-sectional width and thickness. The strength of the frame might be described simply as the depth of this plate times the thickness at the throat, which gives us an areal measure. The thicker and deeper the plate, the stiffer the frame can be. Sometimes on larger gap-frame presses a reinforcing rib is welded around the throat to increase the resistance to deflection.

In designing open-back inclinable (OBI) machines, it is important to have a frame properly designed for "controlled deflection" at maximum tonnage of the machine. This means that, at maximum tonnage, if a perpendicular is

#### For single-action (S) presses:

Capacity of press, tons		Front-to-back dimension of slide or bolster, in.	
SX	XXXX	XXX	XXX
Number of slide connections		Left-to-right dimension of slide or bolster, in.	

#### For double-action (D) presses:

Fig. 4 Designations used for press identification under the JIC classification system

dropped from the slide and from the bed, these lines will intersect at a point approximately at the stock-line height. This then helps to eliminate tooling wear due to the angularity or alligator effect in the machine. It is also interesting to note that in a properly designed OBI machine, its bearings in the frame are set on a 45° angle. This transfers the shaft load directly to the frame and eliminates loading the bolts that attach the bearing caps.

Press builders advocate selection of gap-frame presses of sufficient capacity to perform operations without having to resort to tie-rods for reinforcement. This does not imply that a gap-

frame press cannot be used safely up to its rated capacity. However, where angular deflection may be a determining factor for good die life, such as in the use of large-area blanking dies, conservatism is suggested in selecting a press. Tie-rods extending from the top of the frame to the front corners of the bed can be used to minimize deflection. Because the tie-rods close the gap, the accessibility to the die area and the width of parts fed into the die are limited. Tie-rods can be removed for die setup.

**Straight-Side Presses.** The straight-side frame has the advantage over the gap-frame in that it eliminates angular deflection. Most

straight-side frames are four-piece frames, consisting of the crown, two uprights, and the bed. In most straight-side presses, steel tie-rods hold the base and crown against the columns. As with OBI machines, straight-side frames can be made from cast iron or steel.

Straight-side presses have crankshaft, eccentric-shaft, or eccentric-gear drives (see the section "Slide Actuation in Mechanical Presses" in this article). A single-action straight-side mechanical press is shown in Fig. 5. The slide in this illustration is equipped with air counterbalances to assist the drive in lifting the weight of the slide and the upper die to the top of the stroke. Counterbalance cylinders provide a smooth press operation and easy slide adjustment. Die cushions are used in the bed for blank holding and for ejection of the work.

The straight-side design permits the use of an endless variety of bed and slide sizes. Typical presses may range from 180 kN (20 tonf) capacity and a bed of 510 × 380 mm (20 × 15 in.) to 36 MN (4000 tonf) capacity with a bed as large as 915 cm (360 in.) left-to-right by 455 cm (180 in.) front-to-back. The size and shape of the slide usually determine the number of points of suspension, or connections between the main shaft and the slide, that are needed.

As noted, the straight-side design can provide less deflection under high pressures or off-center loads than does a gap-frame press. The type of work has a great bearing on how stiff the press bed should be. For instance, when carbide tooling is used with close clearances, it is generally felt that it is important to have a stiffer bed to support the lower die shoe. This in turn extends the life of these very expensive dies.

Basically, the straight-side frame has to resist "oil-canning" and twisting with off-center loads. With progressive dies, the load can be, and quite often is, on one side or the other of the centerline. This then imposes a heavier load on one side of the press. Such off-center loads can create unusual conditions in the frame that must be resisted. The instant the press load is applied, this load has to be transferred from the tooling to the slide and through the gibs to the frame. To eliminate twisting, a triple-box construction is used (Fig. 10). Continuous welds running the full length of the press provide high resistance to twisting under load.

As noted, straight-side four piece frames are held together with tie-rods. The relationship among tie-rod stress, frame stress, and press load in a 200 ton (1.8 MN) press is shown in Fig. 11. Line AB shows the increase in tie-rod stress under increasing press loads. Line AD shows the decrease in frame stress under increasing press loads. Point A indicates the stress in the tie-rods and frames as being equal when there is no workload in the press. Point B indicates the stress in the tie-rods when there is no compression left in the frame. (This is the "liftoff" point. The press workload equals the tie-rod load.) Point D indicates zero compressive stress in the frame at the liftoff point. Point C indicates the tensile stress in the tie-rods at the maximum rated tonnage of the

**Fig. 5** Principal components of a single-action straight-side mechanical press. The press shown has a large bed, four-point suspension, and an eccentric drive with counterbalance cylinders. Slide adjustment is motorized.

press. The distance CF indicates the press load at 100% capacity. Point F indicates the compressive stress in the frame at the maximum rated tonnage of the press. Line EB shows what the tie-rod loads would be if the tie-rods were not shrunk. BH shows the rate at which tie-rods will yield beyond the liftoff point.

With the rods assembled through the frame parts, the tie-rod nuts are brought into firm con-

tact with the crown and bed surfaces. The rod is then heated by any one of several accepted methods. As the temperature of the rod increases, its length increases and the lower tie-rod nut moves away from the lower bed surface. When the rod has been sufficiently lengthened by the application of heat, the lower nut is tightened a predetermined amount. As the rod starts to cool, it tends to shrink to its original length but is

prevented from doing so by the semirigid frame parts between the tie-rod nut faces. If the frame parts were absolutely rigid—i.e., if they would not shorten (compress) under the load—the tie rod, when it had cooled off completely, would be stressed in tension to 145 MPa (21 ksi). The frame, of course, would be stressed in compression to a load equal to the tie-rod load.

However, because the frame parts are not absolutely rigid and shorten somewhat under load, the final load equilibrium point between the tie-rods and frame is somewhere between zero and the liftoff point. The exact point of this equilibrium is dependent on the relative stiffness (area and modulus of elasticity) of the tie-rods and the frame parts. In general-purpose press design, this point is targeted to fall somewhere between 90 and 110 MPa (13 and 16 ksi) in the tie-rods. This is, therefore, the residual stress in the tie-rods with a proportionate stress in the frame parts under a no-load press condition. The tie-rods are in tension and the frame parts are in compression. As a workload is developed in the press, the stress in the tie-rods increases while the

**Table 2 Comparison of characteristics of mechanical and hydraulic presses**

Force	Capacity	Stroke length	Slide speed	Control	Preferred uses
<b>Mechanical</b>					
Varies depending on slide position	Practical maximum of ~54 MN (6000 tonf)	Limited	Higher than hydraulic, and can be varied. Highest at midstroke	Full stroke is usually required before reversal.	Preferred for operations requiring maximum pressure near the bottom of the stroke. Preferred for cutting operations such as blanking and piercing, and for relatively shallow forming and drawing (depths to about 102 mm or 4 in.). Good for high-production applications and progressive and transfer die operations
<b>Hydraulic</b>					
Relatively constant (does not depend on slide position)	445 MN (50,000 tonf) or more	Capable of long (2.5 m or 100 in.) strokes	Slower pressing speeds, with rapid advance and retraction. Speed is uniform throughout the stroke.	Adjustable; slide can be reversed at any position.	Good for operations requiring steady pressure throughout the stroke. Preferred for deep drawing, die tryout, flexible-die forming, drawing of irregular-shaped parts, straightening, operations requiring high and variable forces, and operations requiring variable or partial strokes.

stress in the frame parts decreases. This change varies directly as the press workload. Figure 11 shows a simple graphical representation of the

**Fig. 8** Four types of gap-frame presses. (a) Open-back inclinable. (b) Bench press. (c) Adjustable-bed stationary. (d) Open-back stationary.

**Fig. 9** Typical right-to-left shaft-inclinable press frame

relationship among tie-rod stress, frame stress, and press load. The distance GA on the diagram is the stress adjustment in the tie-rods, resulting from the shortening of the frame structure under the load developed in shrinking the tie-rods.

Under full-load press conditions, the tie-rods would exhibit a tensile stress of between 117 and 131 MPa (17 and 19 ksi). This stress is made up of two components: a stress between 45 and 59 MPa (6.5 and 8.5 ksi) holding the frame parts in compression, plus a stress of approximately 72 MPa (10.5 ksi) from the press workload. (Refer to points C and F in Fig. 11.)

In order for the crown to lift off the uprights, the frame parts must decompress completely and return to their original height. For this to occur, it would be necessary to stretch the tie-rods to the length they had attained while they were hot

prior to their shrinking. It is therefore apparent that at the liftoff point, the load in the tie-rods must equal the workload in the press. This commonly is set by design at 150 to 200% of press capacity. Or, stated in other terms, it would require a 50 to 100% press overload to lift the crown from the top of the uprights.

Although the frame members will not separate at their joint surfaces under normal loads, the distance between the bed and the crown will nevertheless increase slightly from no-load to full-load conditions. Note also in Fig. 11 that the tie-rod stress variation is on the order of 20 MPa (3 ksi): from 100 MPa (15 ksi) at no load to 125 MPa (18 ksi) at full load. Such a stress variation is well within the endurance limits of the types of steels from which tie-rods are made, and long tie-rod life may be anticipated provided the rods are properly shrunk.

Overdesigning of press frames for rigidity should also be cautioned. A frame that is too rigid can be as harmful and troublesome as a too-flexible structure. There are, as a matter of fact, a few cases in which frame structures had to be weakened before satisfactory productivity, press life, and die life were possible. The design of a frame is not wholly dependent on the press tonnage. The type of machine, the class of work for which it is intended, the type and construction of the dies that are contemplated, and even the speed of operation all have some bearing on frame-structure design. A frame that is too unyielding can be the cause of very severe damage to dies or to other parts of the press solely because of the commercial tolerance of the stock being run through the press. The tie-rods on all presses serve as some protection against faulty die setting, doubles, and other

**Fig. 10** Triple-box straight-side press frame

**Fig. 11** Relationship among tie-rod stress, frame stress, and press load in a 200 ton press

inaccuracies, but they do not provide safety against breakage of press or die components.

## Mechanical Presses

In most mechanical presses, a flywheel is the major source of energy that is applied to the slides by cranks, gears, eccentrics, or linkages during the working part of the stroke. The flywheel runs continuously and is engaged by the clutch only when a press stroke is needed. In some very large mechanical presses, the drive motor is directly connected to the press shaft, thus eliminating the need for a flywheel and a clutch.

### Press Drives

The drive on a press is made up of the motor/flywheel combination, clutch and brake, and gearing, if used (Fig. 12, 13). Two basic types of drive, gear and nongear, are used to transfer the rotational force of the flywheel to the main shaft of the press.

**Nongear Drive.** In a nongear drive (also known as a flywheel drive), the flywheel is

on the main shaft (Fig. 14a), and its speed, in revolutions per minute, controls the slide speed. Usually press speeds with this type of drive are high, ranging from 60 to 1000 strokes per minute. The main shaft can have a crankshaft, as shown in Fig. 14(a), or an eccentric.

Energy stored in the flywheel should be sufficient to ensure that the reduction in the speed of the flywheel will be no greater than 10% per press stroke. If the energy in the flywheel is not sufficient to maintain this minimum in speed reduction, a gear-driven press should be used.

**Gear drives** (Fig. 14b, c, d) have the flywheel on an auxiliary shaft that drives the main shaft through one or more gear reductions. Either single-reduction or multiple-reduction gear drives are used, depending on size and tonnage requirements. In gear-driven presses, there is more flywheel energy available for doing work than there is in the nongear presses because the speed of the flywheel is higher than that of the main shaft. The flywheel shaft of a gear-driven press often is connected to the main shaft at both ends (Fig. 14c), which results in a more efficient drive.

A single-reduction gear drive develops speeds of 30 to 100 strokes per minute. Speed for a multiple-reduction twin gear drive (Fig. 14d) is

usually 10 to 30 strokes per minute, which provides exceptionally steady pressure.

### Slide Actuation in Mechanical Presses

Rotary motion of the motor shaft on a mechanical press is converted into reciprocating motion of the slides by a crankshaft, eccentric shaft, eccentric-gear drive, knuckle lever drive, rocker arm drive, or toggle mechanism, each of which is discussed subsequently.

**Crankshafts.** The most common mechanical drive for presses with capacities up to 2.7 MN (300 tonf) is the crankshaft drive (Fig. 15). A crankshaft is used in both gap-frame and straight-side presses. The crankshaft drive is used most often in the single-suspension design, although some double-crank (two-point suspension) presses, particularly in the 900 to 1800 kN (100 to 200 tonf) range, also have crankshafts.

**Fig. 12** Types of press drives. The first three press drives, from the left, are called "single-end drives" because the crankshaft is driven from one end only. When the crankshaft is driven from both ends, the drive is termed a "twin drive" (far right).

**Fig. 13** Eccentric-gear drives. Variations of eccentric-gear drives include the double-drive eccentric, the spool gear, and (at far right) the crankshaft with sides of cheeks keyed directly to the main gear.

**Fig. 14** Four types of drive and clutch arrangements for mechanical presses. (a) Nongear (or flywheel) drive. (b) Single-reduction, single-gear drive; clutch in gear. (c) Single-reduction, twin-gear drive; clutch on driveshaft. (d) Multiple-reduction, twin-gear drive; clutch on intermediate shaft

The crankshaft imparts a sine-curve speed relation to the press slide. The stroke of a crankshaft-actuated press can be as short as 25 mm (1 in.), in a small gap-frame press, or as much as 760 mm (30 in.), in a straight-side press. However, most mechanical presses with longer strokes are actuated by an eccentric gear because it provides greater strength. Crankshaft drives are usually limited to strokes of 152 to 305 mm (6 to 12 in.).

The main advantage of a crankshaft-driven press is its lower cost, particularly when capacities do not exceed 2.7 MN (300 tonf).

Points of suspension refer to the number of connections between the slide and the actuating mechanism. Presses can have single-point, two-point, or four-point suspension, depending on the number of points at which the slide is pushed or pulled. The simplest mechanical presses have a pitman that connects the eccentric shaft or the crankshaft to the slide at only one point.

Many wide mechanical presses are built with two-point suspension by connecting the slide to the crankshaft (or eccentric) with two pitmans instead of one, for better distribution of force on the slide.

The largest straight-side mechanical presses usually have four-point suspension for more uniform loading of large slides. Four-point suspension is usually accomplished by two interconnected crankshafts or eccentrics and four pitmans; each pitman is connected near a corner of the slide. Hydraulic presses also can have one,

two, or more points of suspension by operating the slide with as many rams as desired.

**Eccentric shafts** are similar to crankshafts. The eccentric completely fills the space between the supporting bearings of the press crown, thereby eliminating the deflection commonly caused by the unsupported portion where the crank cheeks normally would be. Eccentric drives (Fig. 15) often are used in high-speed, short-stroke, straight-side presses with progressive dies.

The height of the workpiece is the main limitation of the eccentric-shaft drive because the stroke is always equal to twice the eccentricity. When eccentricity is increased, the space available in the press crown determines the maximum stroke that can be used. In most presses of this type, the maximum stroke is usually limited to 152 mm (6 in.). A few presses have been built and used for high-speed operations in which strokes longer than 152 mm (6 in.) were needed. This was accomplished in the press by balancing the eccentric shaft to minimize vibration.

**Eccentric-gear drives** (Fig. 15) are used almost universally for large, straight-side presses that operate at speeds under 50 strokes per minute. In place of a crankshaft, an eccentric is built as an integral part of the press drive gear. The eccentric gear permits strokes as long as 1.3 m (50 in.); however, with such long strokes, speeds are usually only 8 to 16 strokes per minute. With the eccentric as part of the gear, accuracy of alignment of the slide is determined by accuracy

and alignment of the gears. In a two-point suspension, the parallel condition of the ram is determined by the alignment of the driving gears. The principal advantage of the eccentric gear is that it permits greater torque loads at points above the bottom of the stroke. It also permits multiple-point construction with greater versatility and range of stroke length than is possible with a crankshaft.

The chief limitation of the eccentric-gear design is that it usually requires an overhung flywheel. In addition, a single-gear eccentric press usually costs more than a crankshaft or eccentric-shaft press of equal capacity. A further limitation is that eccentric-gear presses are more likely to stick at the bottom of the stroke than are crankshaft presses. Sticking is caused by greater friction in the connector, which is inherent in the large-diameter eccentrics needed for an equal press stroke. Sticking usually occurs during setup if the press is moved slowly until the bottom of the stroke is reached. At this point, a skilled setup man can usually detect whether the press is likely to stick.

**Knuckle lever drives** combine the motions of a crank and knuckle lever to drive the press slide (Fig. 15). Their use is limited to operations such as coining or embossing, in which the work is done almost entirely at the bottom of a short stroke. The knuckle lever mechanism permits large capacity in a relatively small press. High mechanical advantage is inherent at the bottom of the stroke. These presses are rated to deliver full capacity at 1.6 to 6.4 mm ( $1/16$  to  $1/4$  in.) above the bottom of the stroke. The very quick increase in force as the slide nears the bottom of the stroke is the reason its usefulness is limited to operations performed at the bottom of the stroke. Knuckle lever presses usually have capacities of 1.5 to 9 MN (150 to 1000 tonf).

**Rocker arm drives** apply crank or eccentric motion to a rocker arm that is connected to the press slide (Fig. 15). In this mechanism, the linkage is driven by an eccentric gear and a connecting rod. The rocker arm drive is a variation of the knuckle lever drive. However, a press with rocker arm drive is not limited to coining operations; it can also be used for drawing or forming operations.

The rocker arm drive is used mainly in large-bed underdrive presses. The linkage operates from below the press bed and pulls the slide into the work by a link running up through each of the press columns. In most rocker arm drives, the rocker pin and the connecting eccentric pin do not stop in a vertical plane; thus, the load on the eccentric shaft is relieved at the point of maximum load on the slide, and sticking at the bottom of the stroke is prevented. In addition, a high press capacity is obtained because of the mechanical advantage.

**Toggle mechanisms** are the most widely used means of providing the second action in double-action mechanical presses. The toggles operate an outer slide, which clamps the blank against the die, while the punch, operated by the inner slide directly from the crankshaft, performs

Fig. 15 Operating principles of various drive systems for mechanical presses

the draw operation. Principal components of a toggle mechanism are shown in Fig. 15.

### Clutches and Brakes in Mechanical Presses

Both clutches and brakes are essential to the operation of mechanical presses. No other part must work more perfectly if the press is to operate successfully. The clutch must deliver and control the surge of force that is required to shape the work metal. When the press runs continuously, the clutch transmits power from the flywheel to the main shaft. In a single-stroke press, the clutch must accelerate the rotating parts of the drive from stop to full speed at each stroke of the press. Thus, the selection of the proper clutch is dependent on two completely different factors:

- The torque required to deliver adequate force to the slide
- The acceleration of parts that must be started at each stroke of the press

There are two basic types of clutches: positive clutches and friction clutches, as described in this section.

The selection of the brake is dependent on the deceleration of the moving parts that must be stopped at each stroke of the press. The brake must decelerate this moving mass in order to stop the slide at the end of each upstroke. The brake also must be large and efficient enough to stop the press in an emergency, or during inching. Clutches and brakes in presses that are stopped at the end of each stroke need more maintenance than do those in presses operating continuously or that are stopped only a few times a day.

**Positive clutches** are used on many small and medium-size presses (less than 900 kN, or 100 tonf, capacity) and particularly on gap-frame types. Positive clutches always are on the main shaft and use pins, keys, or jaws to lock the shaft and flywheel together. Because they are shaft mounted, they have a minimum mass to move. All positive clutches engage keys, pins, or multiple jaws.

In comparison with friction clutches, which accelerate the press-drive members by slippage of friction surfaces, the acceleration of the drive members by a positive clutch is very rapid because there is no slip. However, it must be remembered that these clutches are always mounted on the crank or eccentric shaft. Therefore, the inertia of the parts that must be started on each stroke of the press is kept relatively low.

These clutches can be arranged for one-stroke or continuous operation, and usually a throw-out cam disengages the keys, pins, or jaws near the top of the stroke. Positive-engagement clutches are either mechanically or pneumatically actuated. Mechanical actuation is ordinarily done by means of a foot treadle, although the treadle can be replaced by an air cylinder. Mechanically operated units can be engaged and disengaged only once for each stroke. They use some type of

throw-out cam or surface to disengage the keys, pins, or jaws near the top of the stroke. The foot treadle releases the throw-out cam and springs engage the driving members to start the press.

An auxiliary cam may be used to release the foot treadle or air-cylinder linkage at a given point of the stroke. Then the press will single stroke even if the treadle linkage is kept actuated. This single-stroking mechanism can be disconnected for continuous operation. The clutch will then remain in engagement as long as the treadle is depressed. These clutches use a drag friction brake, which is usually on and not released during press operation.

Mechanical positive clutches (Fig. 16) cost less than other types and are compact and easy to operate but are limited in many respects and usually require excessive maintenance. They are not recommended for one-stroke work because wear on the clutch would be severe.

Pneumatic positive clutches are much more efficient than their mechanical counterparts. A pneumatic positive clutch is usually a jaw clutch with 16 or more points of engagement. The jaws are engaged by an air cylinder or a diaphragm and are disengaged by springs. No throw-out cams are used. The clutches have electric controls like those used with friction clutches. A press with a pneumatic positive clutch can be used for a single stroke, operated continuously, jogged in either direction, and stopped for emergencies. The brake used with this type of clutch is usually spring operated and air released as a fail-safe measure.

**Friction Clutches and Brakes.** Most friction clutches use air pressure to exert force to clamp friction surfaces together, and the brakes use springs to exert this force. Brakes are air-released. The brakes are spring operated rather than air operated so that the press will stop in the event of a power or air failure. This type of clutch provides relatively shock-free acceleration and deceleration of the press-drive parts.

Friction clutches are preferred to positive clutches for most press applications. Friction clutches may be mounted on the crank or eccentric shaft, the intermediate gear shaft, or the driveshaft, as shown in Fig. 14. The location of the clutch brake unit is determined by factors such as press size, press speed, how fast the press is to be single stroked, type of clutch-brake, and inertia of the press drive.

Friction clutches allow the slides to be stopped or started at any point in the stroke. This makes setting and adjusting dies convenient, especially in large presses. With a well-designed air friction clutch, sudden power failure causes the press to stop immediately. Friction clutches using high-pressure oil or magnetic attraction have been employed to some degree.

Most friction clutches are air engaged and spring released. Brakes are spring engaged and air released. Some clutches are combined with integral brakes; others are constructed as individual units for separate mounting. The brakes for presses equipped with friction clutches are a drum type or single- or multiple-disk type and

are operated in unison with the clutches. Some designs use diaphragms or air tubes for actuation instead of pistons with packings.

One of the greatest advantages of friction clutches is their compatibility with electric and electronic controls. In this respect, they are superior to the positive clutch, with the exception of the pneumatic type.

Two basic types of friction clutches are manufactured: the combination clutch-brake unit in which all parts are assembled on one common sleeve mounted on the shaft, and clutch and brake units separately mounted on the shaft with a single valve for synchronization. As the name denotes, the combination clutch-brake is designed as one unit. A common air chamber is used to operate the clutch and release the brake. This means that the clutch and brake are mechanically synchronized. This design inherently means that most of the clutch-brake parts must be started and stopped each time the press is single stroked, and in a high-inertia design.

With the advent of automation and the much faster single-stroking rates of presses, it became necessary to reduce the stored energy of the parts to be started and stopped by using low-inertia clutches and brakes that are separate units.

**Torque Control.** One important benefit of the modern friction clutch is that it controls torque through air pressure. The torque limitations of a press are determined by the size of the driveshaft, clutch, gears, and crankshaft. A torque load can be imposed when a load is encountered on the upstroke. The press drive has to transmit flywheel energy in the form of torque to the slide. Too great a torque load will cause failures of the torque-carrying members, such as shearing of keys, breaking of gear teeth, and excessive wear of clutch members. The clutch is one link in this torque-transmission chain, which can be controlled and which limits torque overload on the rest of the system. If more torque is required than the clutch can deliver at a rated air pressure, it will slip. This is an important feature of the modern-day press and should be understood in order to take advantage of it in the field.

**Eddy Current Clutches.** A high degree of control over the press is the major advantage of

Fig. 16 Mechanically actuated positive clutch mounted on press crankshaft

eddy current clutches, which are, in reality, press drives. Ram speed at any point on the stroke can be programmed.

Eddy current drives consist of a constant-speed flywheel, a variable-speed clutch-and-brake rotor, and a stationary brake field assembly. The clutch-and-brake rotor is directly connected to the press drive shaft.

Clutching and braking are controlled by the current in the coils. In practice, the press drive is usually controlled automatically to speed up the motion of the slide during the idle portion of the stroke and to slow it down just before the tooling contacts the work.

Hydraulic Presses

Hydrostatic pressure against one or more pistons provides the power for a hydraulic press. Most hydraulic presses have a variable-volume, variable-pressure, concentric-piston pump to provide them with a fast slide opening and closing speed. It also provides a slow working speed at high forming pressure.

The principal components of a typical hydraulic press are shown in Fig. 6. A bolster plate is attached to the bed to support the dies and to guide the pressure pins between the die cushion and the pressure pad. Usually all slides are operated by one pumping system. The relation of each action to the others, interaction, and timing all depend on the controls.

The capacity of a hydraulic press depends on the diameter of the hydraulic pistons and on the rated maximum hydraulic pressure, the latter being a function of the pump pressure and related mechanisms. Hydraulic presses with capacities

up to 445 MN (50,000 tonf) have been built, but most have a capacity of less than 133 MN (15,000 tonf). The typical hydraulic press is rated at 900 kN to 9 MN (100 to 1000 tonf). Gap-frame presses are rated at 45 to 450 kN (5 to 50 tonf).

Because of their construction, hydraulic presses can be custom designed at a relatively low cost. They can be designed with a number of slides and motions, or separate hydraulic circuits can be used for various independent actions. In addition, side action can be provided within the frame of the press by means of separate cylinders. Such side action in a mechanical press is usually provided by cams and is complex and expensive. Most hydraulic presses are straight-side models, but small, fast, gap-type presses designed to compete with mechanical open-back inlinable presses have been developed.

Hydraulic press slides, or platens, are actuated by numerous combinations of hydraulic drives. Hydraulic presses usually have a longer stroke than mechanical presses, and force can be constant throughout the stroke. Hydraulic presses have an adjustable stroke for one or more slides. Accumulators or large-volume pumps can provide fast motion for a slide to open and close. High-pressure pumps provide the working force at a slower speed.

The load pressure of a hydraulic press can be set at any required maximum so that if for any reason this maximum is reached, the press will automatically release itself before any damage occurs. This characteristic is important in drawing aluminum alloys, which have a tendency to work harden. As the metal hardens, the pressure required to draw it increases. Spoilage may be avoided by setting the release pressure low

enough to avoid rupture. Should excessive work hardening occur, the press will automatically release, and the partly formed piece can be removed and annealed. Fluid pressure permits a rapid approach of the punch to the work and the pressure and speed at the time of contact, thus avoiding a blow that might harden the metal. Once contact has been made, the speed at which the draw takes place can be controlled, which makes it possible to make a fairly deep draw in one stroke at low operating speed.

The low speed of the hydraulic press permits the use of low-cost punches and dies because these parts receive little or no shock at the time of contact and comparatively little strain during drawing. Also, the stroke is held (dwells) at the bottom position, which gives the metal time to set and prevents springback to a considerable extent.

When the number of pieces to be produced justifies the cost, hardened steel or mild steel dies and punches may be used, but they must be applied carefully because they are apt to foul because of the adhesion of particles of the sheet to the steel. Satisfactory results can generally be obtained by using zinc alloy dies and punches that can readily be replaced at low cost when they become worn.

Number of Slides

Mechanical and hydraulic presses have one, two, or three slides and are referred to as single-action, double-action, or triple-action presses. Each slide can be moved in a separately controlled motion. Tables 3 and 4 compare advantages and disadvantages of single- and

Table 3 Advantages and disadvantages of single-action hydraulic and mechanical presses

Single-action press type	Advantages	Disadvantages
Hydraulic	Press cannot be overloaded because the system is protected with two separately adjusted relief valves. Full tonnage can be developed through the entire stroke. The tonnage of the press is readily adjustable up to the maximum of its rating, allowing for low-tonnage operation with fragile dies. The stroke is adjustable for the work being done. Die setting is easier because it is not necessary to adjust for material thicknesses or variations in stock. The drawing speed remains constant throughout the stroke. In general, for long-stroke presses, a hydraulic press is less expensive than a mechanical press.	Hydraulic press does not require as much electrical current as a comparable mechanical press, but a much larger motor is required as compared with a mechanical press because there is no flywheel in which energy can be stored. Not generally applicable to blanking operations because the shock of breakthrough is detrimental to piping, gaskets, and press connections, but this disadvantage has been lessened somewhat in recent years through the use of better welding techniques, manifolding, and flexible joints. Generally considered more difficult to maintain than mechanical presses, chiefly because breakdowns of mechanical presses are of the visual type and easily detected, whereas tracing of a hydraulic breakdown requires a thorough understanding of the circuit because the source of trouble is seldom visual. Nested or multiple-die setups are not advisable unless pressures are reasonably well balanced. This is seldom possible.
Mechanical	The single-action mechanical press is faster than the conventional hydraulic press. The mechanical press is by far the most suitable for blanking operations because the breakthrough shock is not detrimental to the machine. Does not require as large a motor as the hydraulic press because it can store energy in the flywheel and then dissipate the energy throughout the press stroke. Can be easily adapted for roll and transfer feeds and for progressive dies. In general, mechanical presses with short strokes are more economical than hydraulic presses.	The single-action mechanical press with cushion has a rated tonnage that is full tonnage a certain distance up—usually 13 mm (1/2 in.) above the bottom of the stroke. Less power is available for work encountered at points above the bottom of the stroke. For instance, a 300-ton (270-tonne) mechanical press with a stroke of 760 mm (30 in.) entering a draw 102 mm (4 in.) above the bottom of the stroke would have an available tonnage of only 114 tons (103 tonnes). At higher points on the stroke, the tonnage factor would be even lower. The mechanical press will not adjust itself for stock variations as does the hydraulic press and thus requires extreme care when setting dies and making allowances for material-thickness variations. If the punch is adjusted too low, the press may stick on dead center. This requires the tedious task of unsticking the press. A single-action mechanical press, when used on a draw that is equal to almost half the stroke, enters the work at the high-midstroke velocity, the drawing speed being reduced as the punch continues downward. This is in direct contrast to the hydraulic press, which slows down before entering the work, then proceeds to draw at a constant rate, giving the metal a chance to flow to its best advantage.

**Table 4 Advantages and disadvantages of double-action hydraulic and mechanical presses**

Double-action press type	Advantages	Disadvantages
<b>Hydraulic</b>	<p>Double-action hydraulic press has four corner blankholder adjustments at the operator's fingertips. The tonnage set on each corner can readily be seen on the control panel.</p> <p>As with the single-action press neither the blankholder nor the punchholder can be overloaded.</p> <p>Full tonnage is available on both punchholder and blankholder throughout the stroke.</p> <p>Tonnage is adjustable on both the punchholder and the blankholder.</p> <p>Full adjustment of stroke is available on both punchholder and blankholder.</p> <p>Die setting is an easier task because no adjustment need be made for material thicknesses or variations in stock.</p> <p>Drawing speeds are constant throughout the stroke.</p> <p>The double-action hydraulic press can be used to perform single-action operations by tying the blankholder and punchholder together to act as one. This is not possible on a double-action mechanical press.</p>	<p>Disadvantages of double-action hydraulic presses are basically the same as those of the single-action hydraulic press (Table 3)</p>
<b>Mechanical</b>	<p>Double-action mechanical presses are generally faster on long strokes than are double-action hydraulic presses.</p> <p>As in the case of the single-action mechanical press, a smaller motor is required.</p> <p>Although maintenance of the double-action mechanical press is much more complicated than that of the single-action mechanical press, it is much less technical than maintenance of the hydraulic presses, particularly the double-action hydraulic press. This advantage is variable, depending on the number of hydraulic presses in the plant and the relative familiarity of the maintenance men with each type.</p>	<p>In comparison with the double-action hydraulic press, much more time and care is required in the adjustment of the double-action mechanical press (as with the single-action mechanical press), due to variations in stock thickness and other factors.</p> <p>The same variations in drawing speed occur with the double-action mechanical press as with the single-action mechanical press, where the tonnage diminishes the higher up on the stroke the work is performed.</p>

double-action presses with mechanical or hydraulic power drives.

A **single-action press** has one reciprocating slide (tool carrier) acting against a fixed bed. Presses of this type, which are the most widely used, can be employed for many different metal-stamping operations, including blanking, embossing, coining, and drawing. Depending on the depth of draw, single-action presses often require the use of a die cushion for blankholding. In such applications, a blankholder ring is depressed by the slide (through pins) against the die cushion, usually mounted in the bed of the press (see the section "Die Cushions" in this article).

Single-action presses, either overdrive or underdrive, are the most commonly used because they are well suited for most press operations. Single-action presses are the simpler of the two types, having only one slide, and are generally more versatile. Although the single-action drive has only one slide motion, cushions can be provided to enable single-action presses to perform blankholding, stripping, knockout, and liftout operations. Various operations can be done with single-action hydraulic presses (Fig. 17).

**Double-action presses** have two slides moving in the same direction against a fixed bed. These slides are generally referred to as the outer (blankholder) slide and the inner (draw) slide. The blankholder slide is a hollow rectangle, while the inner slide is a solid rectangle that reciprocates within the blankholder. With two separate actions provided by two slides—the blankholder for holding the part and the inner slide for drawing—the double-action press is used primarily for deep drawing operations, which would normally cause the part to wrinkle if not held under pressure while being reshaped. Figure 18 illustrates a typical deep-drawing operation with a double-action hydraulic press. Most operations performed on double-action

**Fig. 17** Typical operations of single-action hydraulic presses. In addition to these basic operations, many others can be performed in single-action presses with special adaptations and designs.

**Fig. 18** Typical operation (deep drawing) performed in double-action hydraulic press, shown in three positions of stroke

presses require a cushion either for liftout or for reverse drawing of the stamping.

Deep-drawing operations and irregularly shaped stampings generally require the use of a double-action press. Although the double-action drawing operation can sometimes be accomplished in a single-action press using a cushion as a blankholder, this is generally less practical than using a double-action press. In single-action presses, force is required to depress the cushion. In double-action presses, the blankholder slide has a shorter stroke and dwells at the bottom of its stroke before the punch mounted on the inner slide contacts the work. As a result, practically the entire capacity of the press is available for drawing.

A single-action press also requires considerably more energy to depress the cushion than is required by the blankholder in a double-action press. Therefore, a double-action press can perform a deep-drawing operation with a smaller flywheel and motor. Double-action presses also provide more positive blankholder control and more equal blankholder pressure than are possible with single-action presses. The four corners of the blankholder are individually adjustable so that nonuniform forces can be exerted on the work when required. A double-action press equipped with a die having an open bottom permits pushing the stamping through the die to perform other operations, such as ironing, after drawing.

**A triple-action press** has three moving slides: two slides moving in the same direction as in a double-action press and a third, or lower, slide moving upward through the fixed bed in a direction opposite to the blankholder and inner slides. This action permits reverse drawing, forming, or beading operations against the inner slide while both upper actions are dwelling.

Cycle time for a triple-action press is necessarily longer than it is for a double-action press because of the time required for the third action. Because most drawn stampings require subsequent restriking and/or trimming operations, which are done in faster, single-action presses, most stamping manufacturers consider the triple-action press too slow.

## Press Selection

Important factors influencing the selection of a press include size, force, energy, and speed requirements. The press must be capable of exerting force in the amount, location, and direction, as well as for the length of time, needed to perform the specified operation or operations. Other necessary considerations include the size and geometry of the workpieces, the workpiece material, operation or operations to be performed, number of workpieces to be produced, production rate needed, accuracy and finish requirements, equipment costs, and other factors.

**Size, Force, and Energy Requirements.** Bed and slide areas of the press must be large enough to accommodate the dies to be used and

provide adequate space for die changing and maintenance. Space is required around the dies for accessories such as keepers, pads, cam return springs, and gages; space is also needed for attaching the dies to the press. Shut height of the press, with adjustment, must also be suitable for the dies.

Presses with as short a stroke as possible should be selected because they permit higher-speed operation, thus increasing productivity. Stroke requirements, however, depend on the height of the parts to be produced. Blanking can be done with short strokes, but some forming and drawing operations require long strokes, especially for ejection of parts.

Size and type of press to be selected also depend on the method and direction of feeding; the size of sheet, coil stock, blank, or workpiece to be formed; the type of operation; and the material being formed and its strength. Material or workpiece handling and die accessibility generally determine whether the press should be of gap-frame or straight-side construction and whether it should be inclined or inclinable.

Physical size of a press can be misleading with respect to its capacity. Presses having the same force rating can vary considerably in size depending on differences in length of stroke, pressing speed, and number of strokes per minute.

The force required to perform the desired operations determines press capacity, expressed in tons or kilonewtons (kN) (see the section "Press Capacity" in this article). The position on the stroke at which the force is required and the length of stroke must be considered.

Energy or work (force times distance), expressed in inch-tons or joules (J), varies with the operation. Blanking and punching require the force to be exerted over only a short distance; drawing, forming, and other operations require force application over a longer distance. The major source of energy in mechanical presses is the flywheel, the energy varying with the size and speed of the flywheel. The energy available increases with the square of the flywheel speed.

Possible problems are minimized by selecting a press that has the proper frame capacity, drive motor rating, flywheel energy, and clutch torque capacity.

**Speed Requirements.** Press speed is a relative term that varies with the point of reference. Fast speeds are generally desirable, but they are limited by the operations performed, the distances above stroke bottoms where the forces must be applied, and the stroke lengths. High speed, however, is not necessarily the most efficient or productive. Size and configuration of the workpiece, the material from which it is made, die life, maintenance costs, and other factors must be considered to determine the highest production rate at the lowest cost per workpiece. A lower speed may be more economical because of possible longer production runs with less downtime.

Simple blanking and shallow forming operations, however, can be performed at high speeds. Mechanical presses have been built that operate

to 2000 strokes/min with 25 mm (1 in.) stroke, but applications at this maximum speed are rare. Speeds of 600 to 1400 strokes/min are more common for blanking operations, and thick materials are often blanked at much slower speeds. For drawing operations, contact velocities are critical with respect to the workpiece material, and presses are generally operated at slide speeds from 10 to 300 strokes/min, with the slower speed for longer stroke drawing operations.

## Press Accuracy

Suggested criteria for the accuracy of a press are:

- Maximum tolerances for parallelism between slide and bed; 0.08 mm/m (0.001 in./ft) at the bottom of the stroke for all slides; 0.24 mm/m (0.003 in./ft) at midstroke for punch slides; and 0.4 mm/m (0.005 in./ft) at midstroke for blankholder slides
- Feed, if used, should be accurate within  $\pm 0.076$  mm ( $\pm 0.003$  in.) at 23 m/min (75 ft/min) (see the section "Press Feeds" in this article).
- Gib clearance should be set as close as required to do the job.

**Parallelism.** In a single-point press, the slide guides basically determine parallelism of the slide face with respect to the bed or bolster, both in the front-to-back and right-to-left directions. In a two-point press, slide guides determine parallelism only in the front-to-back direction. Out-of-parallel conditions in the right-to-left direction because of faulty adjusting-screw timing, variations in throw between the cranks or eccentrics, or bicycling (periodic tilting of the slide in opposite directions) due to timing errors in the drive cannot be corrected by adjusting the slide guides.

In a four-point press, parallelism is determined strictly by the press-drive and adjusting-screw accuracy and timing. Out-of-parallel conditions at midstroke, however, can be caused by improper centering of the slide guide adjustment.

**Gib Clearance.** Clearances between press slide guides and gibs are required to compensate for inaccuracies in machining and in the throw and timing of two- and four-point presses, and to allow for expansion and contraction of the guides and gibs. With the bronze-to-cast iron or cast iron-to-cast iron gidding normally used, some slight clearances must also exist for the oil or grease lubricant.

If sufficient clearance is not provided, excessive pressure on the guides occurs at some point during the stroke, resulting in galling of the mating surfaces. The amount of clearance also affects the repetitive registry of punch with die. If the clearance between punch and die is less than the clearance between the press guides, the punch can mount the die, thereby causing premature wear. Clearance between the press guides also depends on the length of the gibs. A reasonable allowance can be 0.08 to 0.15 mm

(0.003 to 0.006 in.), the exact amount varying with gib length. For high-speed presses, the clearance between a gib-type guide and the press slide at normal operating temperature is generally no more than 0.038 mm (0.0015 in.).

Clearances between the mating surfaces of press guides can be reduced by using self-lubricating reinforced-phenolic liners. The modulus of elasticity of this material is about that of steel. As a result, deformation of the liners due to the inaccuracies discussed does not raise excessive compressive stresses in the liners, provided the liners are of sufficient thickness.

Near-zero clearances can be achieved by using preloaded rolling-contact (ball or roller) bearing guides. When offset or lateral loads are encountered, however, tending to cause the press slide to tilt, only a few rolling-contact members at the top and bottom of the guides take the loads. As a result, stresses exerted on the balls or rollers can be very high.

## Press Capacity

Capacity, or rating, of a press is the maximum force that the press can apply. Hydraulic presses can exert maximum force during the full press stroke. Mechanical presses exert maximum force at a specified distance above the bottom of the stroke (usually 1.6 to 13.0 mm, or  $1/16$  to  $1/2$  in.), and the force decreases to a minimum at midstroke.

The tonnage rating of a press may have little relation to the bed area. This is especially true in the automotive and appliance industries, where presses have large bed areas and die spaces but relatively low tonnage ratings. Coining presses have small bed areas and high tonnage ratings.

Overloading of the press can cause damage to both the die and the press. Several devices based on the strain-gage principle have been developed for accurately measuring the load on a mechanical press with a given die. Misfeeds or double blanks are common causes of press overloading. Detectors built into the die stop the press before overloading occurs.

The capacity of a mechanical press involves consideration of the frame capacity, drive capacity, flywheel energy, and motor size.

**Frame Capacity.** The press frame must be able to work at its rating without deflecting beyond predetermined standard limits. For general-purpose applications, the bed deflection should not exceed 0.17 mm/m (0.002 in./ft) between tie-rod centers (or per foot of left-to-right bed dimension on presses without tie-rods) when the rated load is evenly distributed over the middle 60% of the distance between tie-rod centers (or of the left-to-right bed length). Slide deflection should not exceed 0.17 mm/m (0.002 in./ft) between pitman centers when the rated load is evenly distributed between pitmans. Both bending and shear deflections are considered. These specifications can be revised to suit more precise applications.

**Drive capacity** is the capacity a mechanical press develops through the gear train and linkage. The capacity can vary because of the mechanical advantage developed by different types of press linkage and generally is expressed in distance above the bottom of the stroke.

Variation in the capacities of presses with eccentric-gear, crankshaft, or eccentric-shaft drive at any point in the stroke is almost equal. However, the capacity decreases between the bottom of the stroke and midstroke. The capacity of both the knuckle lever drive and the rocker arm drive, however, is much less above the point of rating on the stroke than is that of the crank drives because the knuckle lever drive loses mechanical advantage more rapidly than do crank drives. In addition to loss in capacity, velocity of the slide in the knuckle lever drive and the rocker arm drive is considerably greater at points high above the bottom of the stroke than is the case in the eccentric-gear or crankshaft drives.

**Flywheel energy** for a given job may be insufficient, although the press frame and shaft may be adequately strong. For a greater working distance or for faster operation, more energy and power must be provided.

Blanking operations are completed in a brief portion of the press cycle. The flywheel instantly supplies practically all of the energy required by its resistance to deceleration. The motor may take the remainder of the press cycle to restore lost energy to the flywheel by bringing it back up to speed. Draw operations may take up to one-fourth of the press cycle.

For intermittent operation, 20% is arbitrarily considered the maximum the flywheel may be slowed when energy from it is being used. For continuous operation, 10% is considered the limit because of the short time available to restore lost energy. The low-speed torque characteristics of the press drive motor greatly affect the amount the flywheel can be safely slowed because the ability of the motor to restore lost kinetic energy is a function of these characteristics.

The amount of energy,  $E$ , available at 10% slowdown can be calculated from the following equation:

$$E = \frac{N^2 D^2 W}{5.25 \times 10^9} \quad (\text{Eq 1})$$

where  $E$  is expressed in inch-tons,  $N$  is the rotary speed of the flywheel (rpm),  $D$  is flywheel diameter (inches), and  $W$  is flywheel weight (pounds). The metric version of Eq 1 is:

$$E = \frac{N^2 D^2 W}{6.8 \times 10^6} \quad (\text{Eq 2})$$

where  $E$  is given in kilojoules,  $N$  remains rpm,  $D$  is given in meters, and  $W$  is expressed in kilograms.

If calculation indicates that the flywheel will not furnish the necessary energy, it may be necessary to increase the weight, diameter, or

speed of the flywheel, or to use a different type of drive or motor.

To change the press speed, devices are used to change the speed of the flywheel. The energy of the flywheel is directly proportional to the square of the flywheel speed of rotation. Therefore, the standard energy of a variable-speed press is calculated at its slowest speed. The intended operating speed should be used in checking the suitability of a press for a specific operation.

**Motor Selection.** The primary function of the main drive motor on most mechanical presses is to restore energy to the flywheel. During flywheel slowdown, most of the energy is derived from the flywheel, with some contribution from the motor. Following the working stroke, the motor must restore the energy expended by the flywheel while returning the wheel to speed. If the capacity of the press is not adequate to satisfy the operation, slowdown of the flywheel during the working portion of the stroke becomes excessive, resulting in overloading of the motor. Stoppage of the press can occur if there is insufficient time between production strokes to permit recovery of flywheel speed.

When slowdown is rapid and the working stroke is long, it is desirable to use a high starting torque with relatively low starting current, good heat-dissipating capacity, and sufficient slip (slowdown). The slip designation of a motor is the amount of motor slowdown at rated full-load torque. Under conditions of moderate slowdown and short working strokes, general-purpose motors can be used satisfactorily.

Many presses employ alternating current (ac) induction motors having slip ratings of 3 to 5%, 5 to 8%, or 8 to 13%, the choice depending on flywheel design, press speed, and other parameters. For short-stroke presses operating at speeds above 40 strokes/min, general-purpose motors with a slip rating of 3 to 5% are often satisfactory. Motors with a slip rating of 5 to 8% are often used for press speeds of 20 to 40 strokes/min. For long-stroke presses operating at speeds less than 20 strokes/min high-slip (8 to 13%) motors are usually required.

## Press Accessories

The setup and operation of a mechanical press are made more versatile through the use of built-in accessories. Included are bolster plates, rolling bolster assemblies, speed change mechanisms, shut height adjusters, and slide counterbalances.

**Bolster plates** are used in most hydraulic and mechanical presses, between the bed and the die. They provide a flat surface on which to mount the dies and can be remachined to remove nicks and worn areas. T-slots in the top surface facilitate clamping of the die to the bolster plate. Clearance holes in the bolster plate permit pressure pins to extend from the die cushion to the die. Some press beds have a large hole through the top surface for drop through of parts or for mounting of die cushions. For this reason, bolster

plates are thick to minimize deflection and support the die properly. When parts are ejected through the die, holes of the proper size and location are cut in the bolster.

The width, length, and thickness dimensions of bolster plates have been standardized for each bed size, as have the size and location of T-slots, pressure pin holes, and holes for fastening to the bed. Standardization facilitates interchangeability of dies between presses. Filler plates can be used either above or below the bolster to reduce the shut height of the press. This is in addition to the normal slide adjustment.

**Rolling bolster assemblies** are made for some large straight-side presses for fast tooling change. Dies are set up on an assembly outside the press. When a press run is finished, the punch and blankholder are undamped from the slides and the assembly is moved out of the press. Then, another assembly is moved into place, the punch and blankholder are clamped to the slides, adjustments are made, auxiliary equipment is set up, and the press is made ready to run.

**Speed change drives** are used mostly to change the number of strokes per minute, but some drives also can be used to change speeds during the press stroke for fast approach to the work, slower working stroke, and quick return. Changing speed during the stroke permits an increase in production without increasing the working speed. Press builders commonly supply charts that show the slide speed at any point on the press stroke.

In simple blanking operations, the speed of the working stroke is not critical. In drawing and in some forming operations, the plastic-flow characteristics of the material being formed impose specific speed limitations.

A two-speed drive is combined with clutching and braking in some presses. A clutch can have planetary gears for a two-speed drive. Some two-speed drives have two flywheels with a common brake. With a two-speed gearbox and two speeds from the clutch, a press can have four speeds.

Variable-speed drives may incorporate a speed change belt with adjustable cone pulleys connecting the motor to the flywheel or a steplessly variable electric drive. The eddy current drive, originally developed for inching of mechanical presses, also provides variable speed.

**Shut height adjustment** is provided in mechanical presses to change the distance between the slide and the bed to fit dies of different sizes. Small, single-point presses have a screw arrangement to provide this adjustment. In heavier presses, a gear drive makes it easier for the operator to move the massive slide. As press size increases, this gear drive is motorized. Motorized slide adjustment is used also in many smaller presses. Air counterbalances on most large presses relieve the load of the slide and die from the adjusting mechanism.

Some presses have dials that indicate the shut height in thousandths of an inch. If the dies to be used in the press are similarly marked, die-setting time will be greatly reduced. Other

presses have a motorized adjustment with a dial control. The operator sets the desired shut height, and the slide automatically positions itself.

**Counterbalances** in press slides provide smooth cycling and reduce backlash and gear wear by:

- Counteracting the moving weight of slides, components, and die members attached to the slides
- Reducing the load on the press brake, thus providing faster stopping
- Taking up clearance on the main bearings, reducing the breakthrough shock for cutting operations
- Reducing backlash in the drive gearing
- Easing the adjustment of slides by reducing the load on the adjusting screws

Excessive counterbalance pressure can prevent the normal breathing of bearings and consequently prevent good lubrication of the bearings.

Most presses manufactured with slide counterbalances use pneumatic cylinders as a means of counterbalance, although springs have been used. To prevent too great an increase of pressure through the full range of press stroke, a surge tank is used in conjunction with the cylinders. The tanks are of such a size that the pressure does not increase more than 20 to 25%. A pressure control valve allows the counterbalance pressure

to be adjusted to take care of variation in die weights.

The counterbalance cylinder is attached to the press frame, and the cylinder rod to the press slide. Usually the cylinders are attached to either the crown or the press uprights.

## Die Cushions

Die cushions, often referred to as pressure pads, are used to apply pressure to flat blanks for drawing operations. They also serve as knockout or ejection devices to remove stampings from the dies.

Single-action presses do not have an integral means for blankholding and require the use of cushions or other means of applying uniform pressure to the blanks for drawing operations, except for shallow draws in thick stock. The most common means of pressure control for drawing operations on single-action presses are pneumatic and hydropneumatic die cushions. Figure 19(a) shows a single-action press set up for use with a die cushion.

Double- and triple-action presses feature integral blankholders and do not require cushions for drawing operations. Cushions are sometimes employed on double-action presses, however (Fig. 19b), for ejection of triple-action draws, for keeping the bottoms of the stampings

Fig. 19 Setups incorporating die cushions in (a) single-action and (b) double-action presses

flat or ensuring that they hold their shapes, or for preventing slippage while drawing. For such applications, the cushions must be equipped with locking devices to hold the cushions at the bottom of stroke for a predetermined length of the return stroke of the press slide.

Most die cushions are located in the press beds, but there are applications that require installation within or on the press slides. In either case, the functions are similar, and the operations are the same. The recommended capacity of a die cushion (the amount of force it is capable of exerting) is generally about 15 to 20% of the rated press force. Strokes of the cushions are usually one-half the strokes of the press slides, but should not exceed bolster thickness less than 13 mm (1/2 in.).

Cushions with different strokes and higher capacities are available, but the size of the press bed opening limits the size, type, and capacity of the cushions. Consideration must be given to the press capacity at the point at which the draw is to begin because the force and energy required to depress the cushion is added to that required to draw the stamping. As a result, the force and energy needed for a high-capacity cushion may not leave enough for the operation to be performed.

In **pneumatic cushions**, the maximum pressure is controlled by the diameter and number of cylinders and the available air pressure. Shop-line pressure is generally used, but it is possible to use a booster or intensifier to increase the air pressure. Most cushions are normally rated at a pressure of 690 kPa (100 psi), and it is generally recommended that the pressure not exceed 1380 kPa (200 psi). Surge tanks, if required, must conform to local codes and are generally approved for a maximum pressure of 860 kPa (125 psi).

A pneumatic die cushion for a single-point press normally uses one cylinder and one piston. Two or more cushions may be stacked, however, when a high-capacity unit is required in a limited bed area in which vertical space is available. For multiple-point presses, when the pressure pad area requirement is too large for one cushion, multiple cushions can be arranged alongside one another. The cushions may be individually adjustable or tied together. A multiple-die cushion is often preferable to a hydropneumatic die cushion because of the speed restrictions of the latter. Presses to be used with progressive dies can be equipped with a cushion whose position may be changed from right to left in the press bed.

**Hydropneumatic cushions** are used when higher forces are required or when space does not permit the use of double- or triple-stage cushions. Hydropneumatic cushions are slower acting than the pneumatic cushions; therefore, they are usually used on large presses and on slow presses. They can be adjusted to hold a large, light blank for deep drawing or shallow forming or to grip heavy-gage material as tightly as is required for curved-surface or flat-bottom forming.

A typical hydropneumatic cushion is connected to a surge tank, as shown in Fig. 20. Two individually controlled air lines are required: one connected to the operating valve of the cushion and the other connected to the top of the surge tank. The air pressure supplied to the operating valve determines the capacity of the cushion on the downstroke. The pressure of the air in the surge tank determines the stripping force available on the upstroke. The surge tank may be separate from or integral to the cushion, depending on the space available beneath the press bed.

The pressure of the air in the surge tank is transmitted to the hydraulic fluid, which is free to pass upward through the check valve and force the cushion piston upward. Pressure is also exerted against the face of the operating valve stem, but it is not sufficient to overcome the opposing air pressure working on the operating air piston.

When a downward force is applied to the cushion, the check valve is immediately closed and the pressure of the fluid that is trapped beneath the piston begins to rise. When the pressure against the small face of the operating valve stem reaches a predetermined point, it exceeds the magnitude of the air pressure on the larger area of the air piston and opens the operating valve. As long as the cushion piston continues its downward movement, the fluid beneath it is maintained under constant pressure by the throttling action of the operating valve; the additional fluid replaced by the piston is forced through the valve to the surge tank. Oil pressures are generally limited to approximately 67 MPa (1 ksi).

When the stroke has been completed and the downward force on the cushion piston is removed, the pressure of the fluid beneath the piston is immediately lessened, reducing the air pressure on the air piston, thereby closing the operating valve. Fluid from the surge tank under pressure from the air behind it passes upward through the check valve and raises the cushion piston to top stroke.

## Auxiliary Equipment

Most primary press operations are automated so that equipment for feeding and unloading is used even for fairly short runs. Hand-feeding, with its attendant hazards, is often confined to secondary operations on partly completed workpieces. Goals for planning automated operations should include:

- Maximum safety to the operator and to the equipment
- High or nearly continuous production
- Improved quality of the product and minimum scrap
- Reduction in cost of the finished parts

The shape and position of the part before and after each operation must be carefully studied to

determine whether design changes, such as adding tabs or extra stock to the blank, will facilitate handling.

Automatic handling equipment can be divided into the following categories: feeding equipment, unloading equipment, and transfer equipment.

Coil-handling equipment moves coiled stock to the press area and uncoils it with a minimum of damage to the stock and danger to the tools and operator. Reliable coil handling is important because coil stock is being used increasingly to supply material to presses.

Other auxiliary equipment discussed in this section includes lubricant applicators, straighteners, and levelers.

## Press Feeds

Mechanical feeds are important for high production, combined operations, and operator and press safety. Some feeds supply the presses with stock from a strip or coil; others feed blanks or partly completed workpieces. Either kind, with or without auxiliary hand-feeding, can be used with almost any kind of press. For progressive-die work, the feed length should be accurate and should repeat within  $\pm 0.076$  mm ( $\pm 0.003$  in.). The stock must advance accurately so that the pilot pin can easily enter the piloting hole and position the strip. Too great a variation in feed length could result in distorted pilot holes and scrap parts.

**Feeds for coil stock** feed the work metal from a coil to the press. Choosing the optimum type of feed depends mainly on the type of press, strokes per minute, length of feed per stroke, accuracy needed, and the kind of strip (width, thickness, stiffness, and surface condition). The two most common kinds of feeds are slide and roll feeds.

**Slide feeds** are made in a variety of sizes and capacities. The basic principle of a slide feed is the use of a feed block that is moved between positive stops to advance the material the distance required at each stroke. Slide feeds are very accurate and are particularly suitable for use with coil stock. When strip stock is used, the ends of the strip must be hand-fed into the press.

**Fig. 20** Components and operating principle of a hydropneumatic die cushion

Some slide feeds are powered by the press through an eccentric mounted on the crankshaft extension (Fig. 21). The eccentric can be a simple one-piece unit keyed to the crankshaft, or it can be adjustable to vary the feed in relation to the rotation of the crankshaft. When changes in feed length are frequent, the adjustable type is usually warranted.

The feed block is mounted on hardened slides and either has a feed-blade holder with an adjustable feed blade (usually carbide tipped) or a pair of eccentric gripping cylinders. The material is gripped during the feed stroke and released on the return stroke. Accurate control of feed length is obtained by the use of adjustable stops.

The direction of feed—left to right, right to left, or front to back—is governed by the location of the crankshaft extension on the press and the arrangement of the die. A mechanical slide feed, feeding from left to right on a press with a front-to-back crankshaft, can be provided by using an appropriate linkage. Slide feeds also can be powered by air cylinders or cams on the press slide.

*Roll feeds* are available in sizes suitable for use with almost any width and thickness of stock and are used in every type of presswork, from blanking to complex operations in progressive dies.

A roll feed essentially consists of a pair of rolls that can turn in one direction only. The rolls exert pressure on the stock by the use of springs or

some other device and are rotated by the motion of the press crankshaft.

Roll feeds are suitable for extremely thin material and material with highly polished surfaces. If hard chromium-plated rolls are substituted for standard ground-steel rolls, polished surfaces will not be scored or marked during feeding. Rubber-coated or plastic-coated rolls can be used on soft finished or prepainted stock.

There are two advantages to using roll feeds for feeding thin stock. With patterned rolls, a flange can be formed on a waste edge of the stock as a stiffener. With a single-roll feed, the stock usually is pulled through the die.

The best method of feeding extra-thin stock is the use of double-roll feeds (Fig. 22), in which roll feeds at each side of the die are set so that the stock between them is always under slight tension. Double-roll feeds eliminate manual feeding of end sections when strip stock is processed and are suitable only when a substantial scrap skeleton remains.

Rack-and-pinion-actuated roll feeds are available in almost all sizes but are used mostly in relatively heavy stamping and drawing operations. In larger presses it is common to use double-roll feeds of the rack-and-pinion type that are attached to the press bolster.

**Feeding of blanks** or previously formed stampings to presses is accomplished in several ways. Selection of a specific method depends on many factors, including safety considerations, production requirements, and cost.

*Manual Feeding.* Feeding of blanks or stampings by hand is still a common practice, but this method is generally limited to low-production requirements that do not warrant the cost of automatic or semiautomatic feeds. Manual feeding, however, requires the use of a guard or, if a guard is impossible, hand-feeding tools and a point-of-operation safety device. The use of tools and a safety device eliminates the need for the operator to place hands or fingers within the point of operation and safeguards the operator who inadvertently reaches into the point of operation (see the section “Press Safety” in this article).

*Chute Feeds.* Simple low-cost chutes are often used for feeding small parts, with the blanks or stampings generally sliding by gravity along skid rails in the bottoms of the chutes. Side members guide the workpieces, and rollers are sometimes added to facilitate sliding. Production rates to 1800 parts per hour are not uncommon for gravity chute feeds.

Blanks or stampings are generally placed in the inclined chutes manually, but the setup can be automated by using hoppers, prestacked magazines, or other means to supply the chutes. Windows are provided at the point at which the workpieces enter the chutes when proper orientation is required.

*Push feeds* are used when blanks must be oriented in a specific relation to the die, or when irregularly shaped parts are fed that do not slide down a chute and orient themselves properly in the die nest. Workpieces can be manually placed in a nest in a slide, one at a time, and the slide pushed until the piece falls into the die nest. An interlock is generally provided so that the press cannot be operated until the slide has correctly located the part in the die. Slide length should be sufficient to allow placement of workpieces in the pusher slide nest outside a barrier guard enclosure. Strippers, knockouts, or air can be used to eject finished parts from the die. In some cases, holes can be provided in the bottom plates of the slides through which finished pieces fall on the return stroke of the pusher.

*Transfer Feeds.* In some automated installations, blanks are lifted one at a time from stacks by vacuum or suction cups and moved to the die by transfer units. Separation of the top blank from a stack is usually done magnetically,

Fig. 21 Press-driven slide feed

Fig. 22 Components of a double-roll feed

pneumatically, or mechanically. The top level of a stack can be controlled by a height detection system that regulates a stack-elevating cylinder. Two or more stacks can be arranged to be automatically moved into the elevating station when the previous stack has been used up.

*Dial feeds* are another method of feeding secondary operations that are being increasingly applied because of improved safety provisions and increased productivity. Such feeds consist of rotary indexing tables having nests or fixtures for holding workpieces as they are carried to the press tooling. Parts can be placed in the nests or fixtures at the loading station (away from the point of operation) either manually or by other means, such as with the use of hoppers, chutes, magazines, vibratory feeders, or robots. Dial feeds can be built into or added to presses.

*Industrial robots* are being used extensively for press loading and other industrial applications. These mechanical arms, manipulators, or universal transfer and positioning units are more sophisticated versions of the mechanical hands or swinging arms long used for press loading and unloading (see the section "Press Unloading" in this article). The main difference between these devices and true robots is that true robots can be programmed to perform different operations. Various types of tooling can be attached to the arms to handle different sizes and shapes of workpieces. Not only do such units increase safety, but they also substantially boost production rates. Robots are particularly suitable for low-volume production requirements and for operations in which there are large differences in the size and geometry of the workpieces to be handled.

### Press Unloading

Methods used to unload stampings from presses vary depending on workpiece size, weight, and geometry; production requirements; material from which the stamping is made; press and die design; surface quality requirements; and safety considerations.

**Gravity and Air Ejection.** Gravity is the simplest and least-expensive method of unloading presses, but it is not applicable for many operations. In some cases, dies can be designed so that the stampings fall through a hole in the press bed. The use of open-back inclinable presses facilitates unloading by means of gravity when there are no holes in the beds; stampings fall out of the open backs of the presses. When press inclination is not practical, chutes are sometimes provided to carry the stampings away. Air ejection is still common for light-weight parts but is expensive and noisy.

**Kickers, Lifters, and Shuttle Extractors.** Kickers consist of pivoted levers, generally air actuated, that are mounted in the dies and throw stampings out of the dies when the dies open. Lifters are similar devices but simply move vertically and require other means for stamping ejection. Pan shuttle-type extractors swing to and from the die area, catching stamp-

ings as they are stripped from the punches or upper dies and dropping them outside the presses. Actuation of the pans can be from either the press rams or the independent drives.

**Mechanical hands**, often called iron hands, are actuated by air or electrical mechanisms commonly used to remove stampings from presses. Gripping fingers or jaws are mounted on arms that swing or reciprocate into the die area to lift the stampings and place them on a mechanism for transfer to the next press or operation site. Standard units are available as swing arm or straight-path types.

Interchangeable jaws or fingers are designed to grip the flanges of stampings. Vacuum cups or electromagnetic elements are used in place of jaws or fingers for curved surfaces and fragile or easily damaged workpieces.

**Industrial robots** are also used for press unloading. An important advantage of robots is their programmability to suit various workpieces and requirements.

### Transfer Equipment

Several methods are used to automatically transfer stampings from press to press for high-production requirements. When applicable, the use of chutes on which the stampings slide provides the lowest-cost method. Power-driven slat or belt conveyors are commonly used. Adjustable-speed drives for the conveyors are often desirable to accommodate various cycle times.

**Shuttle-type transfer devices** are used extensively. With some units, the stampings are pushed by reciprocating fingers that extend and retract as required; other units use the lift-and-carry (walking-beam) method. Shuttle units are driven by hydraulic, pneumatic, or electric power, or they are driven mechanically from the press. Adjustable side rails are often provided to accommodate workpieces having different widths.

**Lift-and-Carry Devices.** Figure 23 is an example of a lift-and-carry device. Two rails move into slots milled in a die, rise vertically to lift a stamping from the die, retract and lower to deposit the stamping on a set of idle rails, and return to pick up the next stamping. Each time the presses cycle, the stampings are moved progressively from one press to the next. This type of transfer unit maintains full control of the stampings, from unloading them from one die to loading them into the next die.

**Turnover or turnaround devices** are sometimes added to transfer systems in order to change the positions of the stampings as they pass from one press to another. Turnaround devices generally consist of turntables that lift the stampings, rotate them the required amount, and lower them onto the transfer system. Turnover devices often have one arm and use one or more vacuum cups. In operation, the stamping is transferred to a position above the arm, the arm is raised, the cup or cups engage the stamping, vacuum pulls the stamping against the cups, and

the arm rotates approximately 180°. At the end of the arm movement, the vacuum is released, and the arm returns to its horizontal position. Other devices are of the Ferris wheel type.

**Industrial robots**, electrically interlocked to two or more presses, are also being used for the automatic unloading, transferring, and loading of stampings. Advantages include increased flexibility, with programmability permitting different stampings to be produced over the same press line.

**Computer Numerical Control (CNC).** Transfer systems controlled by programmable CNC units are available for automating press lines. Such systems are independent of the presses, can be adapted to stampings of all sizes, and are easily reset. The transfer slides have integral drives, transfer level is programmable in three coordinates, and transfer rates can be varied along certain sections. Grippers or suction cups are used to handle the stampings. Modular construction of the CNC transfer units permits their use with conveyor belts, buffer storage devices, and turnover or turnaround units.

**Stackers or conveyor loaders** are often provided at the ends of the lines to stack or remove finished stampings that are unloaded from the last press. Low-profile under-the-die conveyors are used for some applications.

### Coil-Handling Equipment

Coil cradles, reels, uncoilers, recoilers, and other types of coil-handling equipment are important to the successful operation of a press.

**Coil cradles** may be either nonpowered or powered. In the nonpowered type, the stock is pulled from the coil by a powered feed, a straightener, or pinch rolls, or by the equipment being fed.

A powered cradle is preferable for coils that weigh more than 900 kg (2000 lb) or when stock is going directly from the reel to the press feed. In a powered cradle, the coil is supported by chain-driven or gear-driven rolls or by a driven conveyor belt. The drive should

Fig. 23 Lift-and-carry transfer device for stampings

be automatically self-equalizing to prevent skidding of the coil.

Coil cradles should have motors that can stand frequent starting of inert loads. A slack loop is created between the coil and the straightener or feed devices by starting and stopping the motor intermittently on signal from a dancer roll, paddle, or other control device. This intermittent operation may cause a standard motor to fail prematurely. With a variable time delay (electronic or adjustable cam), the motor can overrun to a controllable extent after the control has commanded it to stop.

A variable-speed drive reduces the number of starts and stops, prolongs the life of the motor and drive, and often makes it possible to match the speed of the cradle to that of the machine being fed. A clutch can be used so that the motor will run continuously and the slat conveyor or rolls are driven only when stock is required.

**Stock Reels and Uncoilers.** Commercial stock reels can accept coils weighing as much as 22,700 kg (50,000 lb). There are reels of the proper size and type for almost any pressworking application.

Selection of a reel should be based on the maximum coil weight and the widths of stock to be unwound. It is better to overestimate future requirements than to underestimate them and find out later that reel capacity limits improvement in equipment and production methods.

Plain or nonpowered reels are usually adequate when the press feed or stock straightener has pinch rolls with enough gripping power to pull the stock from the reel. When stock is going directly from reel to press feed, the reel should be powered so that the feed does not have the job of both feeding the press and unwinding the coil. If the stock becomes taut between the reel and the feed, the feed may start to advance and the stock may slip, resulting in a short feed length. If a straightener is used between the press feed and the reel, a plain reel can be used. However, materials with low tensile strength and lightweight materials should be unwound from a powered reel; otherwise, they might be stretched between the reel and the feeding device.

Powered reels with variable speed and a loop control are preferred for a smooth operation. Noncontact sensor units, such as photoelectric cells or proximity switches, on the loop control should be used for soft metals, polished surfaces, and prepainted stock. These prevent damage inherent with contact-type (rolling or sliding) sensor units. Without powered reels or loop control, a sudden pull can cause the stock feed to slip and mark the work metal.

**Other equipment** useful for handling coil stock includes recoilers, turnstiles, downlayers, coil cars, coil grabs, and coil ramps.

**Recoilers** are used for winding coil stock after slitting and for winding the scrap skeleton after pressworking.

**Turnstiles** (or horns) are two-arm or three-arm devices used to store coils temporarily before processing. In function, a turnstile resembles a coil ramp. Turnstiles may be

equipped with hydraulic pushoff devices, which add to their speed and efficiency.

**Downlayers**, sometimes called up-enders, are turnover devices for rotating the coil from a horizontal to a vertical position.

**Coil grabs**, for use with cranes, are devices that can handle stock in the horizontal or vertical position. Some similar devices are available for use with forklift trucks. Other devices will pick up a coil and change the position from horizontal to vertical.

**Coil ramps** are inclined storage units for use with reels or cradles. Most coil ramps operate by gravity.

### Other Auxiliary Equipment

**Lubricant Applicators.** In blanking or forming, a lubricant is usually applied to metal that is fed into the press from coils. The lubricant can be swabbed or brushed onto the metal as it leaves the reel, but this is inefficient and wasteful and produces inconsistent results. An automatic applicator improves efficiency and uniformity. The type of applicator used depends on whether the lubricant is a powder or a liquid and, if a liquid, on its viscosity and flow characteristics. Roller coating, drip feeding, and spraying are common. Information on these application methods, as well as on the types of lubricants used, is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

**Straighteners** have upper and lower rolls mounted alternately in a staggered position. The minimum number of rolls that can be used is three; however, five-roll or seven-roll straighteners are most common for the usual range of stock thickness. Straightening of stock less than 0.50 mm (0.020 in.) thick requires additional rolls; as many as 17 have been used for some thin stock.

Some straighteners have a separate screw adjustment for each of the upper rolls; others have one adjustment for the entire series of upper rolls. A straightener should not be overloaded. When stiff, thick metal is passed through a straightener designed for thin metal; it may deflect the rolls permanently or break their shafts. Stiff, thick stock requires larger, stronger rolls spaced well apart. Thin metal requires more straightening rolls than does thick metal. These rolls are usually smaller in diameter and more closely spaced.

Stock straighteners are available in a wide range of capacities and speeds, with either powered or nonpowered straightening rolls. Either the upper or lower set of rolls, or sometimes both sets, is powered. Nonpowered rolls can be used when there is enough pulling or pushing force to get the stock through the rolls. Powered pinch rolls are used to push or pull the stock through the straightener.

Thin stock requires more working to straighten than does thick stock. For this reason, two sets of pinch rolls are used, and all straight-

ening rolls are power driven. The speed of powered straighteners can be adjusted so that the material is delivered by the rolls at the rate it is fed into the press plus 10%. The ideal condition is to have the stock run through the rolls continuously so that there are no breaks or bends in the stock when it is stopped on the rolls. When straighteners are operated intermittently, breaks or bends occur in the stock and are almost impossible to remove.

**Roller levelers**, like straighteners, have staggered pairs of meshing rolls, but the rolls are smaller and more closely spaced. All of the rolls are powered, and some of the upper and lower working rolls have backup rolls. Levelers with backup rolls can impose strains on the metal to remove stack edges or a crowned center. More information on the use of roller levelers is available in the article "Flattening, Leveling, Slitting, and Shearing of Coiled Product" in this Volume.

### Presses for High Production

Mass-produced parts are often formed in presses that are made especially for high-production operation. High speed, or the highest number of strokes per minute, is not the only factor in a high production rate. The capability of a press to run continuously for several hours without full operator attention and with a minimum of wear and vibration contributes more to high productivity than does running at high speed for a short period and then stopping for reconditioning of dies.

The more common types of high-production presses are discussed in this section.

**Dieing machines**, also known as die presses, are set up with conventional progressive dies for long-run operation. These machines are used extensively for the blanking of laminations; however, drawing and forming can be done. The height of the bed above the floor makes it easy to install stacking chutes for laminations and other parts.

Dieing machines are single-action underdrive presses. The drive mechanism for a dieing machine is located beneath the press bed. Four guide rods from a guided lower crosshead pass through bronze bushings in the bed and are fastened to a platen to which the upper die half is attached. The lower crosshead is reciprocated by a crankshaft through connecting rods. By this action, the die halves are pulled together, rather than pushed together, as in a conventional press.

The size of the guide rods and bushings results in excellent die alignment and long die life. The underdrive construction keeps the center of gravity of the press low. The progressive dies mounted in the machine are near eye level, and there are no columns or side members to obstruct the operator's view. Ejection chutes for finished parts and scrap are comparatively high above the floor so that containers are easy to position. Pneumatic cushions, fastened to the top of the

platen for better accessibility for service and adjustment, are used as strippers and blankholders.

Stock is fed through the guide rods with either single- or double-roll feeders. A scrap cutter can be mounted on the end of the machine. Both devices are operated by the upper platen or by a power takeoff on the end of the crankshaft.

**Multiple-slide machines** are fully automatic machines for mass production of small parts from metal strip or wire in coil form. Detailed information on these machines is given in the article "Forming of Steel Strip in Multiple-Slide Machines" in this Volume.

**Transfer Presses.** Performing multiple operations on a single press can increase productivity and decrease costs. Transfer presses eliminate the need for secondary operations; annealing requirements between operations; and in-process inspection, storage, and handling of workpieces.

Transfer presses should be considered whenever 4000 or more identical stampings requiring three or more operations are needed daily. A total production run of 30,000 to 50,000 identical parts is generally economical between tooling changes. Most transfer presses are designed to make more than one part, and they are often used for families of parts that are similar in size, shape, and thickness. One press is being used to produce 22 different parts.

Stampings are being produced in a wide range of sizes and shapes. Any configuration that can be grasped by mechanical fingers is suitable, and the parts do not have to be concentric. Practically any operation that can be done in any other press can be performed on transfer presses. Typical operations include blanking, piercing, forming, trimming, drawing, flanging, embossing, and coining.

Major users of transfer presses are the automotive and appliance industries. Automotive parts produced on these presses include wheel covers, taillight assemblies, control and suspension arms, transmission parts, catalytic converters, and timing-gear case covers. Appliance components include refrigerator, freezer, washer, and dryer parts.

**Fine Blanking Presses.** The fine blanking process is generally performed in special triple-action presses designed specifically for the

purpose. The presses are available in a range of sizes varying in capacity from 220 to 22,000 kN (25 to 2500 tonf) or more.

Basic components of most fine blanking presses are the frame, upper and lower tables for supporting the tooling, a power system, a stock feeder and lubricator, a control system, and a tool safety device. The frames are generally of welded plate construction, with four-column or double-frame web design, but some smaller presses have single-casting frames. Most fine blanking presses are designed for vertical operation of the ram, but horizontal presses are available. On vertical presses, ram movement for shearing is usually upward, but some presses have a downward movement.

**Flexible-Die Forming Presses.** Forming, and sometimes blanking, with flexible dies (rubber pads or diaphragms backed by oil under high pressure) is an economical method because it requires only half a die, and materials of different thicknesses can be formed with the same tool. Also, one pad or diaphragm can be used to produce different workpieces, thereby reducing tooling costs. No scratch marks are produced on the side of the blank facing the flexible die.

Another advantage of flexible-die forming is that localized stress concentrations are avoided because of the uniformly distributed pressure achieved with a rubber pad or diaphragm and the gradual wrapping of the blank around the tool. A limitation is that the process is slower than forming with mating die halves, thus sometimes restricting applications to low-volume requirements. However, depending on workpiece complexity and size, the method may be competitive for part production runs to 20,000.

Flexible-die forming is used extensively by the aircraft and aerospace industries, as well as by other manufacturers with low-volume requirements. The three major types of flexible-die forming are rubber pad, fluid cell, and fluid forming, all of which are performed on either standard or special hydraulic presses. These processes are discussed in the articles "Rubber-Pad Forming and Hydroforming" and "Deep Drawing" in this Volume.

## Press Safety

The safest press is one that operates continuously with a stock feeder and part unloader. This type of machine does not require the full attention of an operator, and there is no need for the operator to reach into the danger area. Flywheels, gears, and other moving parts likely to catch an operator or passerby are usually covered.

For hand feeding, shields should be interlocked with press controls so that the press will not run unless the shields are in place. The best practice is to make the guard or shield a part of the die so that protection is automatically in place when the setup is made or installed. Shields also can be attached to the press frame and adjusted for various kinds of work. These guards should suit all the work done in the press, should be easy for the setup man to adjust, and should give the operator an unobstructed view.

Usually, it is more difficult to guard hand-fed secondary operations because the workpiece requires special handling. However, if production rate and quantity warrant the expenditure, standard or special devices can replace hand feeding of presses.

Available safeguards include barriers or interlocking guards that keep the operator away from danger, sweep and pulling devices that push the operator's hands away, and devices that require both hands to trip the press. All safeguards should be inspected and adjusted before and after every press run.

Important considerations in choosing safety devices are: number of operators at the press, size and type of press, size and shape of workpieces, length of press stroke, and number of strokes per minute. Protective devices cannot do the job by themselves; they should be used with a well-planned and strictly enforced safety program.

## ACKNOWLEDGMENT

Portions of this article were adapted from the book by O.D. Lascoe, *Handbook of Fabrication Processes*, ASM International, 1988.

# Press Brakes

**PRESS BRAKES** (Fig. 1) are a common and versatile type of equipment for bending metal by delivering an accurate vertical force in a confined longitudinal area. Any metal that can be punched or bent by other processes can be formed on a press brake. Press brakes are manually fed by an operator. The operator holds a metal workpiece between a punch and die and against a gage to apply a bend or multiple bends to the metal workpiece. Press brakes can have one of several types of back gages, depth stops, and pins to engage holes in the workpiece. Gages can be manually placed and adjusted, or computer numerically controlled programmable units can automatically adjust settings after each stroke.

A press brake basically consists of two side housings that are held together at the top by a crosspiece and at the bottom by the bed (Fig. 2). The integral parts of a press brake include the housing, brake, bolster plate, bed, ram, gibs, and drive. A ram slides up and down in front of the side housings and does all its work by pressing against the bed. A gibbing and slide arrangement (Fig. 3) keeps the ram supported to the side housings, and two power sources are mounted on both side housings, above the two ends of the ram

to alternately push it down and pull it up during the stroke cycle.

Both the ram and the bed are fitted to accept a wide range of dies for many different operations: bending, flanging, drawing, cutoff, parting, blanking, hemming, curling, staking, notching, coining, piercing, ribbing, lancing, corrugating, beading, seaming, pipe forming, channel forming, embossing, bulging, trimming, perforating, slotting, shearing offsets, seminotching, slitting, louvers, coping, crimping, riveting, and tube forming. Selection of a press brake depends on anticipated production needs in terms of required tonnage (striking force), length of bed, bolster width, stroke length, drive system, and the control system. These choices depend on the material being used, type of operation, and the rate of output. The pressure needed to bend metal on a press brake depends on the hardness and thickness of the metal and the width of the lower die. If the width of the lower die is increased, then less pressure is needed to fill it. Tonnage requirements can rise dramatically with a decrease in the width of the die. The materials generally used on a press brake are low-carbon steel, alloy steel, stainless steel, aluminum alloys, and copper alloys.

Press-brake manufacturers usually offer three alternatives for widening a press brake (Ref 1):

- The press brake can have a wide bolster plate and a removable angle bracket for the ram.
- Both the ram and bolster plate can have angle brackets.
- The ram and bolster plate can have removable angle brackets. This is usually the best choice because it offers greater flexibility.

Widening of a press brake depends on tonnage and the structure of the frame. A large press brake should be widened no more than 915 mm (36 in.) (Ref 1). If work consists of punching and using progressive dies on wide stock in heavier tonnages, then a straight side press with four-point gibbing should be considered instead of a press brake. The straight-side press will have press-brake adaptability with the structural strength of a press. Ram and bed extensions add flexibility to the press brake. Extensions that are

**Fig. 1** Press brakes

**Fig. 2** Schematic illustration of a press brake

**Fig. 3** Cross-sectional view of gibbing and slideway on one end of a press-brake ram

part of the original equipment are better than add-on extensions, because they have the rigidity of factory installation. A press brake used for horning operations such as the closing of box ends should have extensions, preferably on both sides. It is counterproductive to buy a smaller press brake and add on extensions later. It may cause deflection in areas of the bed and ram outside the housings where die shimming will be a problem (Ref 1).

## Mechanical and Hydraulic Press Brakes

Press brakes are divided into two basic categories: mechanical drive systems and hydraulic drive systems. Mechanically driven press brakes have a fixed tonnage and deliver more force at the bottom of its stroke than at the halfway point. Hydraulic press brakes deliver its rated capacity over the entire stroke, and tonnage and ram speed are variable up to the rated limits of a hydraulically driven press brake. A hydraulic drive also allows a longer ram stroke than mechanically driven equipment. Mechanical drives will cycle its ram at more strokes per minute than a hydraulically driven system of the same size. If a user works with dies having a high bottom section, then a hydraulic press brake is recommended. If a machine is needed to exceed its rated tonnage periodically, then a mechanical press brake may be the best choice.

Speed is an important consideration. In the past, only mechanical press brakes were used in high-production shops where product output per hour was important. Later, hydraulic press brakes overcame the slower output rate by adjusting ram speed within a single stroke. Some hydraulic machines offer a third speed that is four times greater than the basic work speed. With this flexibility, the hydraulic press brake can achieve an output rate on long production runs close to comparable mechanically driven press brakes (Ref 1).

**Mechanically Driven Press Brakes.** Mechanical drive systems range from simple, non-gear belt drives to single- and double-gear drives, with mechanical linkages from motor to

flywheel to clutch to gears to crankshaft to crank arm to ram (Fig. 4). They all have one thing in common: a crankshaft action that converts rotary motion into straight, reciprocating motion (Fig. 5). During a stroke cycle, the crank arm drives the ram down to the bottom of the stroke and then back up to the top. An electric motor provides power to a flywheel, which stores energy and provides speed and consistency of motion to the drive shaft on a mechanical system.

Mechanical press brakes have been changed to increase output and for supplying varying ram speed within a single stroke. The ram starts at high speed from the top of the stroke and automatically changes into low speed for the operating position of the stroke. At the bottom of its stroke, the ram again transfers into high speed for its return. A control mechanism provides short, medium, and long periods of time for the ram at slow speeds.

In continuous operation, the ram can be cycled very rapidly for high-speed strokes, due to the mechanical advantage of the crank arm and momentum in the flywheel. The work capability of mechanical drive systems is defined in terms of available tonnage throughout the stroke. Mechanical manufacturers generally cite two reference points for available tonnage: midstroke and bottom-of-stroke (Fig. 6). While the bottom-of-stroke tonnage is the maximum stated tonnage rating for a given press brake, it is not the same as the midstroke, and this difference is due to the nature of the drive system. At midstroke, the crank arm is not in its optimal work position, and the available tonnage is normally approximately two-thirds of the full maximum bottom-of-stroke rating.

As the crank arm continues down from mid-stroke, the available tonnage rises slowly until near the bottom of the stroke, where the available tonnage rises very sharply. This is because the full mechanical advantage of the crank arm appears near and at the bottom of the stroke. A toggle effect is achieved, and the available tonnage can sometimes exceed three times the maximum published rating for the press brake. This is very useful for certain types of operations that are performed within the last few fractions of an inch from the bottom of the stroke. The full rated tonnage is achieved between 3 and 12 mm ( $\sim 1/8$  and  $1/2$  in.) from the bottom, depending on the complexity and quality of the drive system. Joint Industry Conference standards establish minimum distance versus tonnage ratings, and, generally, the more complex and expensive drive systems achieve maximum tonnage ratings higher up the stroke. These criteria apply to mechanical presses as well as press brakes. When press capacity is mentioned in terms of tons, a logical question is at what point above bottom stroke is the stated capacity reached.

The reason this is important is because of the danger of overloading the brake. If the operation being performed on the brake requires tonnage at or near the maximum rating of the brake, it should be performed within this area of maximum available rated tonnage at the bottom of the stroke. If it is performed higher up the stroke, the machine will be in danger of being overloaded because of the design limitation of the drive system. Overload can be very serious and can occur when one is least expecting it, even in routine jobs. Commercially available metal varies in hardness and sometimes thickness from

Fig. 4 Drive mechanism of a mechanical press brake

Fig. 5 Stroke cycle of a mechanical press brake

specification among both pieces and sources. These common variations increase tonnage requirements when they occur. In addition, a simple mistake, such as underestimating the tonnage requirement for a job or inserting two thicknesses of metal, can also increase the tonnage requirement.

Mechanical press brakes should not be used under overload conditions, but not because the machine is incapable of delivering extra tonnage. At the bottom of the stroke, a mechanical press brake can deliver as much as three times its maximum rating. The caution against overloading is given because the drive system and even the structure of the press brake can be damaged by the effect of the extra stresses placed on the mechanical linkages, the slide system, and the frame.

When overload occurs at midstroke, it is sometimes called torque overload because the stresses affect the rotating members of the drive system. When it occurs at the bottom of the stroke, it is termed bottoming overload and is a function of the increased mechanical advantage of the toggling action of the crank arm. Between these extremes, an overload demonstrates characteristics of both.

The speed of a mechanical press brake is cited in terms of strokes per minute and is usually stated without a load for continuous or intermittent operation (Fig. 7). The difference lies in the loss of flywheel energy during operation. Intermittent, or stop-start, operation usually involves just one stroke—that is, the ram cycles down and then back up to the top of the stroke and then stops. This action drains up to 35% of the flywheel energy and causes up to a 30% slowdown of the flywheel. If there is a slight pause before the next stroke cycle, the motor will have time to restore the full energy of the flywheel.

In contrast, under continuous operation, the flywheel loses only approximately 20% of its energy and suffers only approximately a 10% slowdown. This lower energy loss is due to the momentum of the flywheel in continuous cycling, which reduces the energy loss and

makes energy restoration faster and easier. There are formulas available that can aid in selecting a drive system and motor that will result in the least energy loss under load for a given job.

Stroke control is accomplished through operation of a clutch/flywheel engagement. Hand levers, foot treadles, and air-electric controls are available. Different clutch options are available, from mechanical clutches to air-disk assemblies, and even automatic clutch speed-shifting. Generally, the more complex and precise the control, the more expensive the press brake will be. There are special clutch options that permit successive engagement-disengagement of the clutch during the downstroke to allow inching, and other options permit reversal of the motor to withdraw the ram, but generally, the crank arm and ram must bottom before the ram returns upward.

Press brakes allow operators to choose a high-speed process for full cycle of the ram or a fast advance, low-speed bending, and high-speed response of the ram. The mechanical system increases productivity because once the speed is selected, the machine will cycle automatically. Air-friction clutch systems have a higher degree of consistency. Ram leveling is an aid to the user because it saves time in setting up the job. It is standard on most mechanical press brakes. Ram leveling is accomplished by an independent motor linked through a worm gear drive to a pair of adjusting screws inside the rods joining the drive shaft to the press slide. Tilting adjustments are completed by split couplings and clutches that release the drive on one side of the ram. A calibrated device should be furnished at each end of the ram to show the exact position of the side. The air-friction clutch provides a cushioning effect that extends die life.

**Hydraulic press-brake drive systems** (Fig. 8) are relatively less complex than mechanical-drive press brakes. They are comprised of a motor, a pump, a valving system, and a hydraulic cylinder with the piston connected to the ram. The cylinder is usually double-acting—that is, oil is pumped under pressure into the top, above

the piston, to make the ram move down; to make it move up, oil is pumped into the bottom, under the piston. With oil under pressure both above and beneath the piston, the piston is locked in place anywhere in the stroke cycle. The pressure of the oil under the piston is generally held between 10 and 15% of the pressure of the oil above the piston. This is done to keep the ram from dropping by gravity and also to help control the ram throughout the stroke (Fig. 9). The downward movement of the ram during a stroke cycle means that the pressure of the oil entering the cylinder above the piston is much greater than the pressure of the oil underneath the piston. The upward movement of the ram is caused by a reversal of this action. The valving system ensures the desired control and direction of flow either into or out of the cylinder.

The rotary action of the motor in a hydraulic brake serves to drive a pump, which then forces the oil throughout the system. There is no mechanical linkage to translate rotary action into straight, reciprocating action, as in a mechanical press brake. Because the pressure is a steady, controlled flow, the available tonnage of a hydraulic press brake is the same at all points during the downstroke (Fig. 10). The ram can also be instantly stopped, anywhere during the downstroke, by simply releasing the foot pedal. Stroke control is much more precise than in a mechanical brake and involves much more complex action.

Hydraulic press brakes are available with pressing capacities up to 71 MN (8000 tonf). The tonnage of a hydraulic press brake is a function of the size of its cylinders, pump, and circuit capacity. As noted, hydraulic press brakes deliver its rated capacity over the entire stroke, and the applied load and ram speed are variable up to the machine rated limits. A hydraulic press brake also permits much longer strokes for deep drawing, multiple punch-stepping, or large, complex, multiple-action dies. Extralong cylinders can be installed for extremely long strokes, as long as 1.5 m (5 ft). This is not practical on a

Fig. 6 Available tonnage curve for a typical mechanical press brake

Fig. 7 Flywheel slowdown and loss of energy during operation

Fig. 8 Hydraulic press brake with 1.8 m (6 ft) bed length and 440 kN (50 tonf) load capacity with a 4 kW (5 hp) motor

mechanical press brake, because the crankshaft eccentric limits the length of the stroke. Standard strokes on hydraulic brakes are normally at least three times as long as those on mechanical brakes of equal rating.

The length of the hydraulic stroke can also be varied to suit the job that is being done (Fig. 11). Strokes can be as short as 13 mm ( $\frac{1}{2}$  in.). Strokes can be set anywhere throughout the stroke range with limit switches that usually are very easy to set and change. With a shorter stroke, the stroke cycle is faster. For operations requiring very short strokes, such as punching and blanking, a hydraulic press brake can achieve speeds that compare favorably with those of mechanical press brakes, especially when the material is hand fed. Overloading is not

the problem with hydraulic brakes that it is with mechanical brakes. The oil pressure into the cylinders can be set to deliver a given tonnage. Any job requiring more tonnage will cause the ram to stall, but there will be no damage to the press-brake drive system or its structure, because it will not deliver any more than its rated tonnage.

Increasing the pressure of the oil increases the tonnage available on the ram, and hydraulic manufacturers normally build in approximately 10 to 15% reserve as an overload safety feature. However, manufacturers generally do not promote the margins of a safety, so as to curb potential overstressing of the hydraulic system and the structure from too frequent operation in the reserve range.

Fig. 9 Drive system of a hydraulic press brake

Fig. 10 Stroke cycle of a hydraulic press brake

There are different methods to keep the ram level on a hydraulic press brake. Pressure can be exerted by two cylinders powering the ram to keep it level. There are a wide variety of leveling and tilting controls:

- A servo electric system produces a ram tilt condition by a low-voltage electric signal that is increased and fed back to one of the two variable delivery pumps. This system provides continuous correction to the ram level.
- An electronic system uses an electronic sensing device.
- A proportioning valve system checks the flow of fluid to the cylinders, prevents wavering, and offers continuous correction with high accuracy.
- A limit switch uses a steel tape sensor that drives two highly sensitive limit switches through spring-loaded cams.
- A steel tape system enclosed in a glass tube transmits data to a special level-control unit.

All of the aforementioned systems are used for tilting the ram when required by the type of work.

## Bending Capacity

The bending capacity of a hydraulic press brake far exceeds that of a mechanical drive because of its long, full power stroke; it is possible to bend much thicker plate on a hydraulic press brake than on a mechanical brake of the same size. On a hydraulic brake, the chief limitation on bending capacity is the length of the piece to be bent, because of the tonnage requirement. On a mechanical press brake, the limitations include length and thickness, or, in other words, tonnage and stroke (Fig. 12).

As an example, consider the power stroke required to make a  $90^\circ$  air-bend of a given section of mild steel plate in a standard V-die (Fig. 13). The start of the bend requires approximately 80 to 90% of the overall bending tonnage requirement. When the male die achieves a bend close to  $20^\circ$ , most of the work is complete, because the yield point of the metal has been reached. After that, the rest of the bend requires very little increase in tonnage.

Fig. 11 Cylinder in a hydraulic press brake showing adjustable piston travel

The tonnage required to start the bend should be compared with the available tonnage curve for the mechanical press brake to see if it can deliver the tonnage at that point in the stroke without going into overload. If the beginning of the bend is above midstroke, remember that the available tonnage in this area is even less. For heavy plate, from 13 mm ( $\frac{1}{2}$  in.) thick and up, the recommended width of the required die is ten times the thickness of the metal. This puts the beginning of the bend for heavy plate up in the stroke area of a mechanical press brake where it is at a tonnage disadvantage, compared with a hydraulic. Thus, for example, it is possible to bend short lengths of mild steel plate 25 mm (1 in.) thick on a hydraulic press brake as small as 890 kN (100 tonf), over a 255 mm (10 in.) wide V-die,

Fig. 12 Available tonnage curve for a mechanical press brake

requiring a 108 mm ( $\frac{4}{4}$  in.) power bending stroke. In contrast, the smallest mechanical press brake that could perform the same bend in one hit without going into overload would have a 9 MN (1000 tonf) rating and a standard 125 mm (5 in.) stroke (Fig. 14).

For thinner workpieces, mechanical press brakes perform very well with light-gage sheet metal and plate up to 6.4 mm ( $\frac{1}{4}$  in.) thick. Their cycling speeds, especially with automated feeding and unloading equipment, are extremely high. They are particularly suited to long runs of the same bending or forming operation. Small hydraulic brakes, however, have several advantages that compare favorably with small mechanical brakes: an inherent versatility in doing the wider range of operations normally found in metal fabricating shops; precise operating control of the stroke; speed in setup and change-over; flexibility in handling both deep-stroke heavy plate bending and short-stroke sheet metal work; and quiet, shockless operation.

In examining both types of press brakes, tonnage-distribution characteristics also must be considered (Fig. 15). The basic construction involves a long ram with two sources of power, one at each end. The power distribution in this design is the full tonnage of both power sources along the entire length of the ram, as long as the load is distributed along the entire length of the ram. If the load is concentrated in the center of the ram, the full tonnage of both power sources will be available for the load. If the load is concentrated under only one of the power sources, only half the rated tonnage will be available to perform the job (Fig. 16). Moving the load toward the center of the ram permits the other power source to participate in the operation, and

so the available tonnage rises as the load is moved until the short load is exactly centered. At that point, the full tonnage of both power sources is concentrated on the load.

Thus, an operator should not count on the full rated tonnage of the press brake if the tonnage on a short job is concentrated at either end of the machine. When horns are used, the available tonnage drops even more, depending on the horn length and the distance of the load concentration from the power source.

The shape of the ram is designed to resist deflection best in the vertical, left-to-right direction. The depth of the center of the ram adds to its stiffness and rigidity as a beam. This characteristic aids in leveling the ram from right to left. From front to back, however, the ram is relatively weak and is dependent on the gibbing and slideways, which are mounted only on the rear of the ram, at both ends. Front-to-back deflection can be a problem even with a stiffener along the rear length of the ram. Operators should therefore center the load in the dies from front-to-back, especially on press brakes fitted with wide platens. Off-center loads from front to back can cause great stress and may damage the gibbing and slideways, because this is their weak direction.

The shape and mounting of a press-brake ram also leads to a unique advantage in permitting press brakes to be connected in tandem (Fig. 17). Both mechanical and hydraulic press brakes can be so connected to accommodate extralong work. The controls can be designed to permit either machine to be operated independently or both together. Tandems are used when designers specify longer beams and structural forms to minimize welding.

Fig. 14 Comparison of stroke capabilities of two standard press brakes: a 100 ton hydraulic brake (left) and a 1000 ton mechanical brake (right). Work metal: mild steel 25 mm (1 in.) thick by 0.46 m ( $1\frac{1}{2}$  ft) long. Die opening: 255 mm (10 in.) wide. Tonnage requirement: 81 tons. Required bend stroke: 108 mm ( $\frac{4}{4}$  in.)

## Press-Brake Tooling

Press-brake tooling is mounted on the ram with a holder, which is machined to accept a designated style of tooling. Figure 18 shows examples of American-style tooling. Setup of tooling may involve manual clamping and die shimming. Hydraulic clamping systems (Fig. 18)

reduce setup time with automatic clamping and quicker centering and alignment of the tooling.

The two major types of bending methods are air-bending and bottoming. Bottoming dies (Fig. 19) use pressure to cancel out springback, and they are machined to the exact radius desired in the bend; for example, a 90° bottoming die produces a 90° bend. In contrast, air-bending

Fig. 15 Effects of load distribution in a 1000 ton press brake

(a)

(b)

Fig. 16 Typical load distribution from center to thrust forces (a), and forces that act on the ram (b)

dies (Fig. 20) are machined to 88° to produce a 90° bend. Air-bending is commonly used for forming heavy sheets and plates over 10 gage, and bottoming is used only for light-gage forming (approximately 14 gage and lighter) (Fig. 21).

**Gooseneck dies** (Fig. 22) permit forming of two bends close to each other. The die is designed so that the second bend may be made without the die interfering with the return flange. This design, however, makes it mandatory that the die not be overloaded, and thus it should not be bottomed. Gooseneck dies can also be provided with a radius on the tip for other than sharp-corner bends.

**Hemming and seaming dies** can consist of a sharp knife die set and a flat die set. The operation is performed in two strokes, with the knife die making the first bend and the flat die closing up the hem or seam. The flattening stroke requires the most tonnage, and there is often no need to bottom the knife die to produce the required bend.

A hem is a fold at the edge of the sheet metal to remove the burred edge and improve the appearance of the edge. The hem also adds slightly to the rigidity of the edge and improves wear resistance. Hems and seams are shown in Fig. 23(a). A hemming die set is shown in Fig. 23(b).

**Curling and wiring.** Curling and wiring are used to strengthen the edge of sheet metal. Actually, hems, curls, and wiring may be used on flat parts or on round parts such as cams or drums. During wiring, the metal is curled up and over a length of wire. The edge of the sheet metal is strengthened by both the wire and the curl formed in the metal. When the wire is not used, the operation is known as curling or false wiring (Fig. 24). Curling dies are shown in Fig. 25.

**Bead-forming dies** are available for forming two main types of beads: the central bead and the tangential bead. To obtain a good bead in thick material or a small bead in thin material, a wire mandrel should be used during the final closing operation. The wire may be left inside the finished bead or be withdrawn, depending on the final use of the product and the tightness of the bead. It is important when forming the bead to keep the burred edges of the metal to the inside of the bend to avoid scoring of the die surface.

Bottoming methods are not recommended because of the die shapes involved. Generally, the pressure required to form beads without

Fig. 17 Extension of the tandem concept

(a)

(b)

(c)

bottoming is approximately four times that of a standard 90° bend.

**Pipe-forming dies** are not merely scaled-up versions of bead-forming dies. Small tubes or pipes are best formed with three strokes required. Hydraulic press brakes are especially useful in forming pipe because they can be set to hold the pipe closed while the pipe seam is being sealed by tack welding or banding.

**Fig. 19** Principle of a bottoming punch-die set

**Fig. 20** Principle of an air-bending die on a press brake

**Fig. 21** 90° forming punch-die sets for bottoming of light-gage sections

Medium-sized pipe can be bumped progressively on larger-radius dies. Each of the edge quadrants should be formed first and the two center quadrants last. Very large pipes may be formed by this method, using larger-radius dies and forming a half-circle at a time. Two half-circles are then welded together to make a complete pipe section. Large-diameter pipe will probably be too large to fit in the press-brake

**Fig. 22** 90° gooseneck punches

(a)

(b)

**Fig. 23** Examples of (a) hems and seams and (b) hemming die set

**Fig. 24** Curls. (a) Open and closed curls. (b) Wiring and curling

**Fig. 25** Curling dies on a press brake

throat, but it can be accommodated between the side housings or on a horn, depending on its length. An alternative method is to preform the edges in a press brake and form the remainder of the pipe in a roll-former. This method has been successfully used for extremely thick metal that is difficult to get started in the roll-former because of the length of the pipe.

**Channel-forming dies** can consist of a standard V-die set (Fig. 26) or a gooseneck die (Fig. 22), depending on the size of the channel. Two strokes are needed, and each bend should be accurately gaged. This method reduces die cost, minimizes tonnage, and ensures that the bottom and sides of the channel remain flat.

Channels can also be formed in a single stroke, which is not only faster but also more accurate. The drawback is that channel-forming dies are single-purpose dies, are relatively expensive,

**Fig. 26** V-die on a press brake

**Fig. 27** Radius-forming die

and require at least four times the tonnage of 90° air-bends and thus a larger press brake. Production quantities therefore must justify the added expense.

Deep channels are possible with standard V-dies. A reverse bend is made in the center of the metal to open up the channel so that the straight knife die will fit to form the bottom corners. After both bottom corners have been formed, the bottom is straightened to finish the deep channel. Hydraulic press brakes are especially well adapted to this operation, because a long stroke is required to open the dies far enough to remove the part.

**Fig. 28** Offset dies. (a) Typical. (b) Acute-angle offset die. (c) Z-bend offset die

**Radius-Forming Dies.** A standard knife die and V-die set can be used for small-radius bends on sheet metal. The knife die should have a radius no smaller than the required bend radius. As the metal thickness increases, greater allowance must be made for springback because this is an air-bending operation. Larger radii may require a male die with a machined radius. If this radius is approximately 19 mm (3/4 in.) or less, the metal will follow the male die in air-bending over a channel-type die or a simple V-die. If the radius is larger and a full 90° bend is required, the metal will leave the male die as the die moves down. In this case, a matched-bottom-radius die is needed to force the metal back against the male

die contour (Fig. 27). This becomes a bottoming operation with higher tonnage requirements and, of course, added expense for the matched-die set.

Progressive bumping can also be used to form radii in short increments. For best results, the knife die should have a well-rounded nose. To avoid flat sections under the nose of the male die, reducing the V-die opening is recommended. The advantages of this method are low die cost and the ability to compensate for differences in springback. Any desired radius can be formed by adjusting the length of the stroke.

**U-Section Dies.** U-sections can be formed with simple radius dies by the bottoming method or with springloaded pad dies. In both cases, a

second stroke with flat dies may be used to compensate for springback.

**Offset dies** (Fig. 28) can perform two close bends in one stroke, increasing production up to 500% compared with single bends, but the tonnage requirement can range from 3 to 15 times that of a simple 90° bend. Pressures are highest for Z-bends (Fig. 28c) with sharp right-angle corners. Offset dies are also more expensive.

Offset bends can also be made in two strokes with standard V-dies including a narrow bottom V-die to allow clearance for the sheet to fold down. The sheet must be turned over between strokes, but the tonnage requirements are low, and a single standard die size can be used to form many different shapes.

# Die Sets

A DIE ASSEMBLY is a complete punch-press tool that is used to produce large numbers of interchangeable stamped parts. It consists of mating pairs of punches and dies, their retention plates, a stripping device, and a subassembly called a die set. When the press is actuated, the mating components are forcibly brought together to perform the required operations.

The upper die assembly is fastened to the movable press ram, and the lower die assembly is secured to the stationary bolster plate or press bed. The upper member must travel in a precisely controlled path to maintain the alignment and orientation of mating components during the working portion of the press stroke.

Every punch press must permit relative movement between the ram and the press frame in order to satisfy its primary function of delivering energy. The “running” clearance provided, however small, may have an adverse effect on the operational alignment of mating punch-and-die combinations. For example, even when press parts are closely fitted and precisely aligned, the running clearance may actually exceed the required punch-to-die clearances within the die assembly.

The impact nature of the forming process further complicates the alignment problem. It generates deflecting forces that must be effectively opposed so that alignment can be maintained.

Obviously, the alignment system of the press requires that the die assembly provide additional guidance and support at the point of impact and throughout the working cycle. It is in this area that a good die set demonstrates but one facet of its tremendous value.

**Caution:** Although the die set can be relied on for the ultimate alignment, it cannot be expected to compensate for a press in poor condition or to operate properly if subjected to heavy deflecting loads.

The guide post/guide bushing combinations, properly fitted, ensure precise control of the movable member at every critical point of the stroke to maintain the relative position of each pair of mating components.

## Functional Requirements

A good die set is not just a subassembly. It provides the foundation for a basic working

system on which a press tool can be assembled, aligned, inspected, and put into operation. It enables the die builder to assemble many separate components into a single integral unit that provides many cost-saving benefits:

- *Ease and accuracy of setup:* The die assembly is installed in the press as a single unit, which minimizes setup time and ensures proper alignment of mating components.
- *Improved and consistent stamped-part quality:* The ensured accuracy of each setup maintains the original degree of punch-to-die clearance uniformity and thereby enhances piece-part quality.
- *Increased die life:* Correct register of punch-to-die reduces the rate of wear on both components and minimizes the risk of component breakage.
- *Ease of die maintenance:* Cutting components can be sharpened in assembly, as units, without removing them from the die set—a distinct advantage over removing the components and sharpening them individually.
- *Simplified die-repair procedures:* Broken or worn components can be removed and replaced without disturbing their relative positions. Alignment and orientation of mating components is virtually ensured.

## Die-Set Nomenclature

The die set is a modular unit consisting of a stationary lower plate (die holder), a moveable upper plate (punch holder), and at least two sets of precisely fitted guide posts and guide bushings. Smaller die sets are equipped with a projecting stem (shank) that extends from the top surface of the punch holder (Fig. 1).

Generally, the guide bushings are assembled to the punch holder and the guide posts to the die holder. This arrangement is normally reversed when ball-bearing bushing assemblies are used.

## The Shank: Functions and Variations

The shank is used to center the die assembly in the press and to secure the upper die member to the press ram. A large die set may also be equipped with a shank, but it should be used only for centering purposes—not to secure the upper die assembly to the ram.

The shank may be an integral part of the punch holder or it may be a separate unit that is secured by means of a threaded end or individual fasteners. Integrally welded shanks are structurally stronger, cannot loosen in operation, and provide the least interference with knockouts or with adjacent fasteners and components.

Floating shanks are designed to compensate for a ram face that is not perpendicular to the cavity for the die set shank. The top of the punch holder is machined to receive a swivel adapter that contains a separate shank. The shank is permitted to move until it conforms with the ram face. Parallelism between the punch holder and the die holder is not affected.

## Alignment Considerations

The die set is expected to maintain the alignment of all mating components during the die-building stage and throughout the productive life of the die assembly. In essence, a good die set must withstand the rigors of use without prematurely losing its ability to control alignment.

Many factors must be considered and controlled in order to satisfy this objective:

- Dimensional specifications and limits
- Allowances for cylindrical fits
- Material types related to the various die-set components
- Geometrical deviations that may be anticipated
- Permissible variations in the alignment of guide posts and guide bushings
- Available styles of die sets and components

**Fig. 1** Die-set nomenclature

ASME B5.25 (B5.25 M), "Punch and Die Sets," provides detailed data for each of the foregoing factors.

Functionally, standards data provide product definition by means of materials specifications, dimensions, and permissible tolerances. In this sense, they tend to establish an area or range from which selections can be made. They fail, however, to provide the basis on which to make a selection.

## Application Requirements

The ultimate alignment of mating punches and dies cannot be better than that provided in the die set. Alignment must be established during the building stage when practically no deflecting loads are applied. Alignment must be maintained when the tool is in operation and producing stamped parts.

Under operating conditions, the entire die set and the individual components are continuously subjected to high-impact loads and deflection forces. Consequently, all selections should be predicated on the basis of resistance to shock, deflection, and wear.

## Punch and Die Holders

These plates must satisfactorily oppose rapidly applied compression loads. The plate material must have high compressive strength and toughness. Because the die holder may be mounted on parallels or span large bolster-plate openings, it must also exhibit a high degree of stiffness or resistance to bending. The ability to resist these forces is largely dependent on the material selected and the physical proportions of the plates. In general, rigidity increases with plate thickness.

Because of the need for many fastener holes and extensive machining operations, the plate should be free from such internal defects as porosity, hard spots, or shrinkage.

When a die set requires milled pockets, large counterbores, cutouts, or burnouts, the plate should be stress relieved. It is recommended that

the die-set manufacturer perform the machining before the plates are bored for guide posts and guide bushings.

Based on these considerations, the most widely used plate materials are:

- Hot-rolled steel containing 0.15 to 0.30% C and 0.30 to 0.90% Mn
- Gray or cast iron and specialized irons such as Meehanite (Meehanite Metal Corp., Mequon, WI)
- A combination wherein one die-set member is made of steel and the other is cast iron
- Tool steels (hardened or partially hardened), aluminum, magnesium, and other special alloys

The steel plate and the specialized irons are the most popular materials. Of the two, the advantages of all steel die sets are clearly established:

- Greatest resistance to impact loads and to loads that are not uniformly distributed
- More uniform density
- Ability to be flame cut and welded

## Plate Flatness and Parallelism

The opposite surfaces of the individual plates must be both flat and parallel to avoid an adverse effect on the ultimate alignment of mating components (Fig. 2).

Components mounted on a surface that is not flat may cause the line of action to be canted away from the perpendicular and result in sheared or broken cutting edges. Should a component be assembled over a small bump in the surface, a rocking action may be imparted by the punching load, causing component breakage or premature wear.

Punch-to-die alignment will be impaired if the opposite surfaces of a plate are not parallel even though both may be flat (Fig. 3). The components will be tipped away from the perpendicular, and the lines of action of the upper and lower die assemblies cannot coincide.

Parallelism parameters are applicable to the assembled die set as well as the individual plates (Fig. 4).

## Guide Posts and Guide Bushings

Guide posts and guide bushings, in combination, establish and control the path followed by the movable upper die assembly. In effect, alignment uniformity can be maintained only when the relative positions of the upper and lower die members remain unchanged during the working portions of the stroke.

Because deflecting forces are always present and can be minimized but not eliminated, the selection of guide posts and bushings must be based on their ability to resist both wear and deflection (Fig. 5).

Two basic guidance systems enjoy a marked degree of popularity: the ball-bearing bushing assembly and the more widely used conventional system. Each has advantages as well as disadvantages, and selection is usually a function of personal preference.

The ball-bearing bushing assembly, by virtue of its rolling balls, provides unusual ease of assembly. The interference fit or preload on the balls maintains the relative position of the bushing to the post, but the assembly is less

Fig. 2 Plate flatness

Fig. 3 Plate parallelism

Fig. 4 Die-set parallelism

Fig. 5 Guide post/guide bushing deflection

resistant to deflecting loads. For a given bushing size, the post is more likely to bend because its diameter has been reduced in order to provide room for the balls. To compensate for this problem, some die sets maintain the basic guide-post diameter and increase the bushing size. The plate dimensions are correspondingly increased so that the available die space is unchanged. Rolling balls generate less friction than sliding members but are more difficult to lubricate (Fig. 6).

The interference fit with the individual balls eliminates any possibility of a physical barrier being established between the components. Ordinary lubricants will break down due to extremely high pressures that rupture the film. It is necessary to use extreme-pressure additives that react with the various components to form chemical barriers that prevent metal-to-metal point contacts (Fig. 7).

Ball-bearing bushing assemblies are recommended during the building phase, but the post and ball cage can be removed and replaced with the conventional demountable post for optimal performance.

In the conventional system, clearance is provided between the post and the bushing. This space is then filled with lubricant to provide a physical barrier between the moving members. The Die Set Standard establishes the permissible range of clearance without adversely affecting alignment ability and defines the configuration of the lubricant-retention grooves. Guide posts and bushings are prefitted to dimensions, within tolerance, and are furnished as matched units in each die set. By means of color-coded components and selective assembly, three classes of operating fits may be specified.

Guide posts and bushings are subjected primarily to frictional forces, which generate wear. Even deflecting forces are translated into wear factors because they tend to break down the lubricant and thereby increase the coefficient of friction between the sliding members. In selecting the best combination of materials for use in a

specific application, the decision is dependent on the anticipated operating conditions:

- **Frequency, amount, and type of lubrication:** Lubrication must be performed on a regular schedule, and the amount must be adequate to replace the lubricant that has been displaced or used. When large deflecting forces are anticipated or encountered, extreme-pressure additives are required.
- **Punch-to-die clearances to be maintained by the die set:** When clearances are extremely close, the guide post and bushing must be selected on the basis of abrasion resistance. Hardened steel posts and bushings are selected for the majority of applications.
- **Condition of the press:** Specially processed bronze-plated bushings should be chosen when considerable ram play is anticipated. These bushings provide a bronze interface with a steel support and are used with hardened steel posts.
- **Velocity of operation:** Press velocity is not merely expressed in terms of strokes per minute. In actuality, it is the product of twice the stroke multiplied by the number of strokes per minute. Bronze-plated bushings and chromium-plated guide posts are the best choice for high-speed operations.
- **Abrasive impurities in the surrounding atmosphere:** When the surrounding atmosphere is charged with abrasive particles that cannot be removed economically, well-lubricated hardened steel guide posts and bushings will provide the best service. The hardness is such that the abrasive particles will have less effect on surfaces.

Surface wear due to friction, either sliding or rolling, is referred to as abrasive wear. Should the abrasive wear condition be permitted to continue without alleviation, the ultimate result will be seizure: the normally moving members will be literally welded together.

## Abrasive Wear in Die Sets

When relative motion exists between two parallel, lubricated surfaces, the protective film is subjected to stretching as well as compressive forces. As a result, there is almost never a complete protective film separating the surfaces. Minute voids in the lubricant film permit metal-to-metal point contacts to occur. These point contacts, along with hard foreign elements in the

lubricant, induce an abrasive action on the two surfaces. The result is a removal and/or relocation of surface material caused by a small-scale welding action between contacting points. In its extreme form, this surface relocation action results in seizure.

A periodic visual examination of guide posts and bushings is recommended. In many cases, abrasive wear can be detected by the polished appearance of the surfaces, and corrective action can be initiated to prevent seizure.

Abrasive wear is the result of the frictional forces developed during the relative movement of the two members. It is extremely significant to note that friction cannot be present unless the two surfaces are forced together by the application of an external load. In effect, the conventional post, and bushing combination, are subjected only to deflecting forces; the ball-bearing bushing assembly is subjected to the initial load imparted by the interference fit plus the deflecting forces.

Guide-post and guide-bushing materials must be selected relative to the lowest frictional coefficients and the greatest resistance to deformation. The objective, of course, is to select material combinations that offer the greatest wear resistance with the least rate of wear. To determine which materials best satisfy the objective, a number of mechanical and physical properties must be considered.

**Relative Hardness.** Where relative sliding action occurs, it is generally agreed that the greater the hardness difference between the two members, the lower is the coefficient of friction. In the presence of hard foreign elements, however, a harder surface on both members will generally provide a lower wear rate. The ability of a material to bury within itself various amounts of foreign particles increases as its hardness decreases. This characteristic is particularly desirable because the abrasive particles are eliminated from the immediate region where the surfaces may be in contact. Die-set operational requirements, however, preclude the use of a very soft material for its embeddability characteristics alone. A layer thick enough to absorb a substantial quantity of particles would soon be plastically and permanently deformed by the lateral pressures imposed by deflecting forces.

**Elastic and Plastic Characteristics.** Hardened materials exhibit the greatest resistance to deformation. Their relatively high elastic limit permits them to withstand large lateral loads with a minimum of distortion. Soft materials may be permanently distorted when subjected to similar loading conditions. Their relatively low elastic limit may be exceeded, resulting in plastic deformation or displacement. Experiments conducted in a range of low operating pressures and velocities have demonstrated conclusively that hardened steel bushings are more wear resistant than those made of a cast alloy containing zinc, aluminum, and copper. In both instances, the mating surface was a hardened steel guide post.

**Presence and Characteristics of Surface Films.** Lubricants tend to fail when subjected to

Fig. 6 Guide-post rigidity comparison between ball-bearing and conventional guidance system

Fig. 7 Ball-bearing deformation

large pressures and/or high velocities. When the lubricant film is ruptured, metal-to-metal point contacts occur. Extreme-pressure additives such as chlorine and sulfur combine with the base materials to form a chemical film or barrier that can reduce substantially the rate of wear. It is also possible to introduce a thin metallic film having a low coefficient of friction at the interface of the two surfaces. Specially processed bronze-plated bushings exemplify this approach and exhibit an extremely low rate of wear.

#### Ability to Form a Common Welded Joint.

As stated previously, seizure is an extreme form of abrasive wear. It is typified by considerable surface material removal and/or relocation and drastic increases in frictional forces and is usually accompanied by an audible squealing sound. The point at which this action occurs and the extent of damage to the bearing surfaces are largely dependent on the physical properties of the materials involved. Because high local surface temperatures are generated, there is some flow of bearing material, generally resulting in a galled appearance. If the local heating produces a welding effect between minute quantities of the two materials, the strength properties of the resultant substance will influence the degree and direction of the galling. Materials, therefore, should be selected on the basis of least affinity for each other and, in the event of a welding action, the lowest strength properties in the resultant substance. An indication of the properties of the formed alloy will be given by its relative position in the periodic table.

### Geometrical Considerations

Guide posts and bushings are secured to the appropriate plates by means of press fitting or the use of external toe clamps and fasteners. Components assembled by the latter method are known as demountable items.

The demountable components provide the best guidance system because all of the desirable geometrical requirements are maintained (Fig. 8). In addition, they can be easily removed and replaced to simplify die-maintenance procedures without disturbing the initial alignment.

The use of a wring or a light tap fit between the plate and the bushing or post, for a length of approximately 4.8 mm ( $\frac{3}{16}$  in.), practically eliminates distortion in any of the components. The guide bushings are machine honed for accurate hole geometry and size. They are then mounted on arbors so that the shoulder seats can be ground flat and perpendicular to the guide posts. This combination of manufacturing accuracy and distortion-free assembly automatically squares up the posts and bushings to the die-set surfaces.

The holes bored in the die-set plates serve only to position the posts and bushings. Retention is accomplished by means of toe clamps and cap screws, which develop greater resistance to stripping than do press-fitted components.

In press-fitted assemblies, the plate holes must provide for the retention of the guide posts and bushings as well as their relative positions. The interference between the bushing and the hole in the plate distorts the bushing hole. The subsequent honing operation may bell-mouth or enlarge the entry end, resulting in loss of proper fit.

Press-hole distortion is an inherent risk in press-fitting operations. Consequently, the posts and bushings may not be square with the die-set surfaces. It may be necessary to tap the components to adjust the grip for squareness.

### Abrasion and Seizure Testing Methods

A single unit consisting of a guide post and bushing was installed in a fixture with a variable-speed motor drive that made available speeds of 50 to 430 strokes per minute. The bushing was split into halves to facilitate the application

of variable surface loads. Accurately calibrated strain gages were used to measure the magnitudes of the applied loads. Lubrication and cleanliness conditions were maintained as uniformly as possible throughout the experiment.

The graph in Fig. 9 illustrates the effects of press speed and variable surface loads on the coefficient of friction between the sliding members.

### Endurance Testing

A special die set was installed in a mechanical press continuously operated at 320 strokes per minute. Variable surface loads were applied to the guide post and bushing assembly by means of a preloaded compression spring. Lubrication was introduced between the guide post and bushing at the beginning of each test run, and operation was continued until seizure occurred.

Following each seizure, the specimens were allowed to cool, examined for galling,

Fig. 8 (a) Demountable and (b) press-fit guide post and bushings

Fig. 9 Hardened steel bushing characteristics (stroke length, 25 mm, or 1 in.)

relubricated if galling was not too severe, and reoperated to determine whether a healing characteristic existed.

This test demonstrated the superior wear resistance of hardened steel posts and bushings. This combination will maintain close tolerances for long periods of time when loads and speeds are below the point of seizure.

### Die-Set Recommendations

Catalog die sets that provide up to 635 by 355 mm (25 by 14 in.) of die space are offered in many guide post and bushing arrangements.

They include many styles and types of guide post and bushing designs from press-fitted and demountable types to the ball-bearing bushing assembly. Both commercial and precision die sets are available for selection.

The broad areas for selections do not impose any unusual die-design restrictions, and the advantages of die layout for catalog die-set usage are many:

- The punch or die holder can be replaced if necessary.
- Worn or damaged guide posts or bushings can be replaced without impairing the original alignment.

- All steel punch and die holders are stress relieved to maintain dimensional stability during subsequent machining operations. It also helps to soften edges that may have become hard during the flame-cutting operation.

### ACKNOWLEDGMENT

This article was adapted from the chapter “Die Sets: Applications and Functional Requirements” by O.D. Lascoe in *Handbook of Fabrication Processes*, ASM International, 1988.

# Press Feeders

A STAMPING JOB SHOP generally begins with the installation of a press. Either a reel or a stock cradle is added to handle coiled material. If labor costs are low, the material is pushed into the die by hand, but as labor costs increase, it becomes more and more important to automate the feeding operation.

There are four basic types of feeding arrangements: hand feeding, hitch feeds, roll feeds, and slide feeds. Hand feeding is most useful for short runs and those special cases where secondary sheets and precut lengths can be used to offset the higher cost of coil stock.

Of the automatic feeds, the hitch-type feed is the oldest and least-expensive mechanism. In this type of feed, the material is advanced by a wedging action between a blade and a moving block. These units are best at feeding medium-weight materials at relatively short progressions. Because of the low cost of some commercially available hitch feeds, they are often attached directly to a die where the setup can be of a permanent nature.

A popular type of permanently mounted equipment is the roll feed. In this unit, the material is advanced by the pressure of two opposing rollers, one or both of which are driven from the crankshaft of the press. These units are generally best for feeding rigid materials in moderate to heavy thicknesses. Thinner materials can often be handled by using a double-roll-feed combination in which a set of feeding rollers is attached to each side of a press and synchronized by a connecting link. Roll and mechanical slide feeds generally offer the longest life and highest speeds available today but represent a permanent installation at prices ranging from moderate to high.

Slide feeds fall somewhere between the hitch feed and the roll feed in cost and have the capability of handling materials including the very thin and the very compressible. Air slide feeds are not limited to use in punch presses but can be mounted on special machines in almost any position and can be actuated by mechanical, electrical, or air signals.

Because of the versatility of the air feed, we will examine various feeding concepts for the job shop utilizing air-operated punch-press feeds. The operating principles of air feeds are general and can be applied directly to hitch feeds and roll feeds. The problems that arise in the use of air-operated punch-press feeds are also encountered with other types of feeds. Note that

if the proper precautions are followed, almost any type of feed, within its limitations, will give good accuracy, speed, and utility. Before considering a switch from one type of feed to another, always examine the application. The feed at hand is usually capable of doing the job if it is given the proper opportunity.

## Types of Material

Automatic feeds are normally designed to feed standard coil stock. If the stock is rigid enough to resist clamping or roller pressure and is self-supporting, it falls into the classification of a standard material. This is the type of material normally found in production shops. In addition to these materials, job shops are often called upon to feed materials not easily accommodated by the production installation.

The simplest special shape is wire. Almost all types of feeds will easily handle wire unless the wire diameter is very small—usually less than 0.38 mm (0.015 in.). The clamping and roller pressures relative to the area of the wire become so high at small diameters that deformation of the wire often occurs. The air feed, with its high clamping area, simplifies this type of feeding job. For small diameters, it is sometimes necessary to use telescoping tube guides to prevent buckling of the wire as it passes through the feed and the die. As the wire diameter becomes smaller, the

job becomes more difficult and more delicate, but by no means impossible (Fig. 1).

Thin materials (thicknesses less than about 0.38 mm, or 0.015 in.) have been difficult to feed. Flexible inserts in the clamps can usually prevent scratching of highly polished materials, but again, depending on progression and the self-supporting features of the material, it may be advisable to install antibuckling guides or other types of support for the material as it passes through the feed. Small air feeds excel at feeding thin material.

The ease of grinding special shapes in the clamps makes air feeding of special formed material a simple operation. If the form is rigid, passageways can be machined to accommodate almost any shape. If the form becomes very high, it may be necessary to add special inserts or to machine special clamps—again, a relatively simple operation. Compressible and stretchable materials present a different type of problem. If a material is so flexible that it is distorted and stretched merely by being held in the hands, it will cause considerable feeding problems. Nonetheless, this type of material must be fed, and probably the most practical solution is to bond the material, in a temporary manner, to some sort of carrier strip. This could be, perhaps, a paper carrier approximately the thickness of card stock (but, of course, in coil form).

Compressible materials are best handled by machining a cavity in a clamp slightly smaller in height than the thickness, and slightly larger than

**Fig. 1** Telescoping antibuckling guides for wire

the width, of the material. The amount of difference depends on each individual application, but the basic idea is to let the clamp bottom on the feed yet slightly compress the material in order to use the friction of the material to resist the feeding forces. The ease of doing this type of job depends on the resistance of the material to deformation. Proper and imaginative techniques can simplify a difficult job (Fig. 2).

If more than one strip of material is to be fed, it is necessary to grip each piece individually. Again, the air feed makes this a simple job. There are many ways of gripping each individual strip. Among the favorites are use of a flexible insert in the clamp and use of a spring pin to grip each strip (Fig. 3).

Feeds that accommodate strips cut to precut lengths are not as common in the job shop. This type of feed is generally available at a very high price for companies that specialize in high production of special parts. Typical of such parts are the tops for bottles. Usually the press and the feed are available as an integrated package. If the job shop is called upon to handle strips, it must use its ingenuity, and, because hand feeding is often the best method, it should not be overlooked. Encountered in feeding of strips is the problem of what to do with the material between the feed and the die. A simple solution—but one that is relatively expensive and not always applicable—is to use two feeds, one mounted on each side of the die. The strip, of course, must be longer than the distance between the two feeds. Other methods involve either automatic or hand placing of one strip behind the other, perhaps using tape to fasten the strips together as they are running automatically.

Fig. 2 Clamp design for compressible materials

## Air Feeds

Air feeds offer the utility of use with a wide variety of presses and machines. Their ease of installation and removal expands their versatility because they can be quickly changed from one die set to another. Often the actuating bracket can be left on the die and the feed can be moved from one job to another within a few minutes by removing two bolts and reinstalling the feed on another unit. The many available methods of actuation make air feeds quite simple to use on impact presses, electric presses, hydraulic presses, wire-forming machines, multislide machines, and special machines that bear little relationship to actual presses.

**Mounting of Air Feeds.** Air feeds typically have almost no mounting limitations. Although they are generally mounted either directly on the die set or on the bolster plate of a press, they can also be attached to the feed vertically, sideways, or upside-down. One common application is to mount two feeds on one die or special machine and process and assemble two different parts. Consider also the possibility of mounting an air feed on a movable platform such as the punch holder of a die set. In one application, two punch-press feeds were mounted one behind the other, thus giving the progression capabilities of two separate increments, depending on which unit was signaled (Fig. 4).

**Air-Feed Actuation.** There are two basic methods of actuation for air feeds: internal and external. Internal actuation, by means of the mechanical valve built into the feed, is normally used on average-stroke presses for normal conditions. It is the simplest and the preferred method of actuation.

If the stroke of the press becomes extremely short or long, or if special conditions exist, external actuation may be required. This consists of either electric or air actuation in which the mechanical valve is replaced with an electric or air valve mounted as close to the feed as possible. Of course, this external valve must be triggered by a microswitch or air pilot valve generally mounted so as to be operated by a rotary cam on the crankshaft or a linear cam on the ram of the

press. This method is most useful on special machines where a slide may not be adjacent to the feed, or in circumstances where long or short press strokes are being used. Although electric actuation is the most convenient method of external actuation, the cam-operated air valve offers a particular advantage on some special machines, especially where there is danger from electric arcs (Fig. 5).

Most air feeds allow some means of over-travel of the valve mechanism. Normally, the valve switches in the first fraction of an inch of travel, and over-travel is provided to ensure that the feed has time for retraction at the bottom of the stroke. The bottom portion of the stroke is, in most instances, useless for feeding purposes because the punches are perforating the material or forming the part. As the die opens, the feed can be triggered to push the material into the die. A general rule of thumb is to allow 50% of the cycle for feeding and 50% for retraction. This is best accomplished by using the bottom half of the press movement for retraction of the feed. The mechanical valve attached to an air feed accomplishes this condition automatically, but the wide range of variable conditions available with electric actuation calls for greater care in the selection of the actual feeding and retraction signals.

This great versatility in mounting and actuation allows automatic feeding in machinery not normally adaptable to the use of standard feeds.

## Types of Jobs

The stamping job shop must have the flexibility to accommodate many different types of jobs. Job shops are called upon to run high-production and low-production jobs and must make a profit on both. In a typical application, two different parts are made from two pieces of material in a single die and are assembled in the final station. Two or more feeds, mounted either at opposite ends of the die or at right angles, are used. The simplified mounting of air feeds again aids in this type of installation. Often a very high-production machine will use literally dozens of air feeds.

**Jobs Involving Rewinding.** Often the job shop is faced with the realization that the

Fig. 3 Simultaneous feeding of two strips of material

Fig. 4 Rapid-air feed mounted on die set

completion of a part in a single die will be expensive for a short run. A solution is to run the material through one die, rewind it on a rewind reel, and then pass it through a second die for the secondary operation. Several good makes of rewind reels are available, but the major problem is generally the axial location of the material from one operation to another. The cumulative error will be enough to scrap the parts; therefore, a pilot is the only solution. The pilot can be placed either in the die or on one of the clamps. Again, the versatility of machining special shapes on the clamps of an air feed simplifies this otherwise rather difficult operation (Fig. 6).

**Long progressions** present a problem in that long-stroke feeds cost a great deal of money. A relatively simple solution for long progressions is to provide a multistroking device. At the end of the set number of progressions, the feed will stop and provide an electric signal for use in actuating the press. Although this approach is less expensive than buying an extremely long feed, it does have the disadvantage of reducing the available number of strokes per minute. A formula that has been found to be helpful for determining the speed of such a combination states that the number of strokes per minute is equal to  $x/2N - 1$ , where  $x$  is the speed of the feed at the maximum progression and  $N$  is the number of progressions. For example, if the regular speed for a 300 mm (12 in.) progression is 100 strokes per minute, and it is desired to feed three 300 mm (12 in.) progressions for a total progression of 915 mm (36 in.), the approximate available speed is  $100/2(3) - 1$ , or 20 strokes per minute. At this speed, the feed is generally operating more slowly than the press, but the job can usually be done at an economic cost.

Another popular use of a counting device is to feed a given number of times before actuating

another secondary operation such as a separate cutoff. This is commonly done in the making of such parts as radiator fins. Instead of a counter, consider the use of a microswitch. This is another example of a simple solution to what could otherwise be a complicated problem.

**Separate Progressions.** Another somewhat related problem is feeding of two separate and distinct progressions, either alternately or in some sort of fixed sequence. This is difficult with regular hitch feeds or roll feeds, but with a little ingenuity, the air feed, with its reciprocating action between two fixed stops, can provide a solution. Either an air cylinder or a solenoid is used to insert a block of a fixed length between the regular stop on the feed and the sliding block. Generally, two progressions are required, but the solution could be expanded to accommodate a reasonable number of different progressions. The insertion of the fixed block must be timed to occur when the feed is in its forward position, and the actuating means must be fast enough to accomplish the job without interference. The control can be as simple as a push button operated by the press operator or can be electrically programmed. The choice again depends on the length of the job involved.

**Continuously Adjustable Progressions.** A situation rarely but sometimes encountered in the job shop is the problem of providing a continuously adjustable progression. This is relatively difficult. Although this procedure requires a great deal of work and diligence, it can result, if successful, in a great increase in production. Typical applications are the feeding of pre-printed paper forms to be cut out into individual pieces and the feeding of materials such as labels to be sewn into clothing. The technique begins with an electric eye that detects a light or dark spot on the part. The electric eye operates a

solenoid or air cylinder that adjusts the fine-adjusting screw on the feed to a progression either slightly longer or slightly shorter than necessary. For example, if the electric eye is set to feed long on white material, the overfeeding will eventually allow a control spot to work its way into the range of the electric eye. When the control spot reduces the reflection from the built-in lamp to a minimum level, the electric eye provides a different type of signal, which, through valving or solenoids, adjusts the progression of the feed to a shorter progression. The control spot will gradually recede from the range of the electric eye until the cycle again reverses. The degree of accuracy is relative to the type of electric eye and amplifying system used. This procedure is relatively complicated and, although not beyond the scope of the job shop, should be used only in high-production situations.

## Accuracy Control Techniques

The two main reasons for using automatic press feeds are to improve production and to provide uniform, accurate progressions. In some cases, accuracy is not important, but in others it can be the entire reason for using automatic feeds. All press feeds have accuracy limitations. Some are more easily adapted to overcoming these limitations, but accuracy generally can be improved in any feed by using the same techniques.

The simplest accuracy control is a positive or dead stop. When an automatic feed with a positive stop is used, the progression of the feed should be set for a distance slightly greater than the actual progression. This will ensure that the

Fig. 5 Electric valve mounted on rapid-air feed

Fig. 6 Hydraulic payout and rewind reel

material always moves the required progression. In order to use this type of stop, the material must be cut off in the last station. The amount of material cut off controls the progression, and thus positive stops can be quite accurate on rigid material. However, this method is ineffective in controlling the progression of thin or compressible materials (Fig. 7).

The most common type of accuracy control is done with pilots. In this operation, a hole, generally round, is pierced in the material, and then, in a subsequent station, a punch with a rounded nose is inserted into the material, aligning it in the proper position. Pilots can be used for both axial and lateral control. In order to avoid uncorrectable axial errors, it is best for the pilot to engage the material in the station immediately following the piercing operation. When a pilot is used with an automatic feed, the usual suggestion is to feed the material slightly short and allow the pilot to pull it into the proper position. Thus, any feeding device should have the capability of pulling material through with just a slight amount of force. Again, pilots are effective on relatively rigid materials, but their performance drops considerably when they are used to feed thin or compressible materials (Fig. 8).

Disappearing stops are related to pilots in that they engage some edge or hole in the strip as it passes through a progressive die. They are generally less expensive than pilots, but do not offer the same accuracy control.

Perhaps the simplest means of controlling accuracy is to rely on the feed itself. Proper attention must be given to control of various factors that affect accuracy, but, with good conditions, repeatability much better than  $\pm 0.025$  mm ( $\pm 0.001$  in.) can be achieved. We will now discuss various factors that must be checked in order to provide maximum accuracy.

The greatest accuracy is achieved when the feed is used only for feeding and is not made to serve some dual purpose. Most readers will be

aware of the problems associated with non-powered straighteners, but little attention is generally given to the effects of using non-powered reels. The difficulty that arises when material is pulled directly off a reel comes from the inertia of the coil. At higher speeds, the jerk necessary to start the reel rotating is enough to cause either slipping or stretching of the material. For this reason, it is almost always best to pull the material from a free loop hanging between the feed and the reel or straightener. This loop should contain enough material for three or more progressions. Generally, automatic payoff devices are used to provide this loop, but in simple installations an operator can rotate the reel, or a weighted roller can be hung on the material between the feed and the reel (Fig. 9).

Another cause of apparent inaccuracy in feeding is the shear force generated at the cutoff station in a die. This shear force is generally not present when holes or forms are being pierced through the material but is always present when parts are cut off before some restraining punch or pilot has engaged the material. The feed must then resist this force, and although in many cases it can, the best solution—not only for the sake of the feed, but also for die life—is to provide a holddown clamp in the die that grips the material before the shearing action takes place. The

heavier the material, the more pronounced is the shear force (Fig. 10).

In many forming dies, the material is pulled up and down as a part is being formed. This means that the material must be pulled slightly through the feed and then pushed backward. This situation should be avoided in die design, but if it is present, the feed must be mounted as far away from the die as practical so as to maintain the integrity of the geometry to an acceptable level. Somewhat related to this problem is the pulling of material as a part is being drawn. Of course, we are all familiar with the use of cutouts in a strip to reduce this problem (Fig. 11).

Mechanical interference often causes inaccuracy of an elusive nature. It is obvious that camber of the material will cause binding due to failure of the material to pass through the die itself. This type of problem can also occur as a result of improper alignment of the die and feed. Often this alignment is not square because slight differences in the shape or size of the material, or differences existing as the material passes through the feed, can sometimes cause the material to be pushed at a slight angle. The best solution is to observe the results in the die and adjust the feed accordingly. Although a powerful air feed can overcome some of these limitations, it is always advisable to provide the best conditions possible. The possibility of slugs in the die affecting accuracy should not be overlooked. Often a feed will push the slugs aside, but only after the restriction has affected the accuracy. Slugs can be particularly troublesome, and often very difficult to correct, depending on material characteristics. There are commercial devices available to aid in slug removal. Otherwise, the standard die-making techniques should be used to eliminate this problem (Fig. 12, 13).

Hitch feeds and air-operated punch-press feeds require that the impact at the end of the forward stroke be reduced to the minimum. The better air feeds have various devices such

Fig. 7 Positive stop

Fig. 8 Distortion of thin material by pilot

Fig. 9 Powered pedestal-type stock straightener

Fig. 10 Shear force on cutoff

Fig. 11 Pulling of stock during forming operation

as speed-control valves and cushion pistons designed into the unit. Impact-reducing materials such as rubber and urethane can also be used as cushions. Generally, these techniques are quite simple, but if they are not followed, the material will continue to move forward due to inertia after the feed has stopped. Inertial slippage often will be accentuated by oily material. Although this problem can be reduced by overpowering the system with heavy clamps, this procedure often leads to deformation of the material. A better solution is to provide a material with a high coefficient of friction. Leather is one of the better materials for clamp inserts because it is slightly compressible and will not mark the stock. It provides a high coefficient of friction even under oily conditions.

Some of the most difficult materials to feed by any method are stretchable materials. Often a double-feed combination is the simplest way to accomplish feeding of such materials. One feed is mounted on each side of the press, with the exit feed set at a slightly longer progression. Actuation, of course, must be simultaneous, and a mechanical link often connects the sliding portions of each feed. Because stretchable materials do not lend themselves to feeding without buckling, special guides can be used. Consider also the possibility of using tension reels to keep the material taut as it passes through the working stations.

## Special Speeds

High-speed feeding is popular because it is the most obvious and attractive way to reduce the costs of a part. Air feeds are capable of speeds up to approximately 500 strokes per minute at a 13 mm (1/2 in.) progression. Beyond this it is best to rely on the mechanical advantage of a roll feed or on a specialized high-speed feed. These units are usually expensive and should be considered as part of a total package with a good, well-built, high-speed press. The problems encountered with such units are different, and for high production their advantages can be rewarding.

Very low speeds are also sometimes required, typically for handling extremely delicate materials. Air feeds often are called upon to provide extremely slow, uniform feeding, such as feeding of solder into a furnace at a continuous, smooth rate. The air feed provides a very inexpensive solution to this problem. The low speed is usually controlled by a separate speed-control valve.

## Air Circuits

Effective use of machinery requires that its operating principles and functions be thoroughly understood. Air feeds usually appear complicated but only because the valves and moving parts are inside the unit and thus not visible.

There are a few simple principles, the understanding of which will greatly increase one's ability to analyze problems and make effective use of air-feed equipment.

The air feed is divided into two separate air circuits. The first circuit is controlled by the main valve, which operates both sets of clamps. The stationary clamp is used to prevent the friction of the slide block from dragging the material backward as the feed retracts for a new progression. The movable clamp provides the greatest force for gripping and pushing the material into the die. The clamp portion of the circuit can be considered as follows. When the main control valve is depressed, the air is exhausted from the clamp circuit. As the pressure falls, the stationary clamp grips the material just before the movable clamp releases. As the main valve is allowed to come up, the action reverses and the movable clamp grips the material just before the stationary clamp opens. The clamps move in sequence by a balance between the areas as determined by the designer of the feed. If it is desired to add motion to this cycle, a pressure-sensing valve is added to the circuit. This auxiliary or pilot-operated valve allows a flow of air into or out of one side of the piston. The area of the pilot-operated valve is adjusted so that the feeding cycle takes place at the appropriate time; retraction occurs while the feed clamp is down. This general principle allows great flexibility in feeding because the two separate circuits ensure that the clamping cycle takes place before the feeding cycle. It also aids in separating the two air circuits so that the pressures necessary for clamping are not greatly reduced by the air flow necessary for feeding.

Fig. 12 Binding of stock between feed and die

Fig. 13 Slug pickup

## Maintenance and Life

Any piece of machinery must be properly maintained for maximum performance and long life. There is no reason why an air feed cannot provide hundreds of millions of cycles. In fact, many feeds provide more than 100 million cycles per year. Needless to say, lubrication and air supply are the key factors to long feed life.

Many shops have a problem with water in the air lines. This is caused by compression of relatively moist air and subsequent condensation of liquid when the air is cooled by being passed through the pipes to its point of use in the shop. Although many extensive systems are installed to eliminate water, generally for the job shop the simplest methods are the best. An after-cooler at the compressor will eliminate most of the water. There is a simple solution to this problem that should not be overlooked: turning the outlet tee in an upward direction and drawing the air from the top of the pipe (Fig. 14).

Most air feeds are built to operate for many millions of cycles before O-rings or seals require replacement. In order to promote the longest life for moving seals, a filter should be used to keep the air as clean as possible. The lubricator should be set to provide a small amount of light machine oil for lubrication. Under good conditions, an O-ring life of at least ten million cycles can be expected. Under excellent conditions, O-ring life is considerably better.

There is no need to use "fancy" oils. One of the least-expensive oils will work best. It should be remembered that motor oils are designed for automobiles and spindle oils are designed for precision spindles. Air feeds use inexpensive No. 10-weight hydraulic or machine oil. A periodic maintenance schedule will provide optimum service. Manufacturers' suggestions

Fig. 14 Air lines with tee down and tee on top

should be consulted for best results from maintenance schedules.

## General Job-Shop Problems

The job shop is called upon to make many types of dies. Some shops specialize in high production and others in very short runs. Therefore, the problems of the job shop vary so much that it is hard to specify general rules. There are, however, some universal suggestions that come up often enough to warrant comment—especially because these problems apply to automatic feeds of many different types.

In the straight cutoff-type die, the shear force can push the material backward. In fact, in hand feeding of heavier-gage materials, a considerable shock can be felt in the operator's arm and hand. Pressure pads should be used in the die to prevent this problem.

In dies where bending is performed, careful attention must be given to preventing projections in the strip from catching on cavities on the die. This will lead directly to buckling problems in the die and inaccuracy in feeding. Workers should be cautious of the friction generated by tight bends around forming mandrels. Feeding equipment is usually strong enough to overcome this type of friction, but, depending on the size of the unit and the nature of the stock, inaccuracies can result.

In forming and drawing dies, it is best that the level of material remain constant. Often this is difficult, and the best rule in such cases is to mount the feed as far away from the die as possible. It should be noted that this is exactly opposite to the normal recommendation.

A type of die not to be overlooked in today's production shop is the transfer die. This die is helpful in forming parts around arbors or in performing multiple bends. The part is generally carried in a strip to the next-to-last station, where

a bend is made and the part cut off. The part is then pushed by an air cylinder to the final station, where final forming or assembly is performed.

In any job-shop operation, the length of the run and the setup are of primary importance. It would be convenient if dies and feeds could be mounted on presses permanently. Unfortunately, this would be rather expensive because most jobs are simply not that long. Thus, setup time becomes extremely critical, and air feeds can serve a very useful function. Most air feeds can be completely set up in a matter of minutes and can be moved from press to press or die to die with very little difficulty.

## ACKNOWLEDGMENT

This article was adapted from the chapter "Press Feeders for the Job Shop" by O.D. Lascoe in *Handbook of Fabrication Processes*, ASM International, 1988.

# Multiple-Slide Machines and Tooling

THE MULTIPLE-SLIDE MACHINE, sometimes called a four-way, four-slide, or multislide machine, is a somewhat specialized item of stamping equipment, although it is very versatile within a limited area of stamping applications. From the design standpoint, a multiple-slide machine may be described as a horizontal stamping press using a system of cam-controlled tools for producing small parts from coil stock.

Numerous small parts are produced by these machines. In addition to stampings from sheet metal, these machines are used to fabricate parts from wire. Brackets, clips, electrical connectors, and clamps are typical of the types of stampings made on such machines.

## Machine Construction

The design of a multiple-slide machine is a radical departure from the normal concept of pressworking mechanisms. Nevertheless, the basic principle used in shaping and cutting of stampings is the same as that of any conventional press. Moving slides, fitted with suitable tools, strike the metal while it is supported on tools equivalent to dies, forcing it to assume the desired shape. The base of the multiple-slide machine is essentially a large steel table. A hole is provided near the center of the surface through which completed parts are discharged.

The driving mechanism of the machine consists of an electric motor that is linked by gears or belts to the shafts that operate the tools. The shafting arrangement is the most unusual characteristic of the machine. It consists of four shafts that completely surround the bed of the machine to form a rectangle. The shafts are connected at all four corners of this rectangle by gears. Power is applied at one point of the shaft arrangement and, due to the gearing, gives motion to all four shafts. The slides of the press are connected to cams mounted on the shafts. Split-type cams are often used for this purpose to facilitate conversion to various jobs.

Through this shafting arrangement, slides can be introduced to the die area from all four sides of the press. In addition, several slides may be attached to each shaft, increasing the flexibility

of the machine and the number of operations that may be performed. It should be noted that the motion of the slides is in the horizontal plane, another departure from the conventional method of pressworking.

Another important component of the multiple-slide machine is the piercing head. Die sets for piercing, cutting, trimming, blanking, or embossing are mounted in this head. The die components are mounted on edge on a solid backup plate. The punch plate retains the punch components and is mounted on a slide driven by cams on the front shaft. Stock is fed from the left side of the press. Sometimes, two or more piercing heads may be mounted on a single press. The slides for these heads may be mounted on either the front or rear shaft, providing flexibility in tooling. For instance, a burr resulting from the piercing operation may be located on the desired side of the part by locating the tooling on the proper ram. The piercing head is actuated by solid-type cams for reasons of strength. In addition, the cams used in this application are not changed as frequently as are other cams.

After being formed, the part is stripped from the forming tools or the post and dropped from the press.

## Advantages of Multiple-Slide Machines

Multiple-slide machines perform in a manner similar to presses equipped for progressive or transfer operations—that is, a number of separate operations, usually all the operations necessary to complete the part, are accomplished in a single machine. In fact, due to its method of operation, this machine may perform the full sequence of operations on a part that could not be completed in a single conventional press, even though transfer or progressive dies were used. This minimizes the number of presses needed to produce a stamping and provides the added advantages of reduced handling costs and conservation of floor space.

The primary advantage of four-slide machines is their versatility, meaningful because it can result in reduced unit part cost. Rapid changes can be made in the combination of press and forming operations, and production can be

shifted quickly from one part to another. Forming operations are more flexible than similar operations on power stamping presses because the stroke, shape, and timing of each forming tool can be adjusted independently. For example, changes in the design of a strip part can often be accomplished by single tool adjustments. In a stamping press, an entirely new die may be needed.

In general, press parts require relatively little forming. The parts are quite simple and do not necessarily have a strip shape. Four-slide parts are more complex, involve a higher degree of forming, and usually have the basic strip shape integrated in their design. Despite these differences, four-slide machines and high-speed stamping presses have some common production characteristics:

- High volume
- Low-cost materials (standard mill product strip and wire stock)
- Predictable material strength characteristics
- Uniformity of parts
- Excellent surface finish (surface appearance of original stock is retained)

Other comparisons of four-slide operations with press operations are described next.

**Production Speed.** Four-slide machines have a wide range of output rates in parts per hour. The production rate depends on the material and the forming operations. Presses are capable of output rates as high as those of four-slides on simple parts, but parts that require complex forming can be produced at higher speeds on four-slides.

**Tooling Cost.** Because the tool motions in a four-slide are already built into the machine, toolmaking is confined to shaping of the working surfaces of cams, center forms, and slide tools. In progressive-die forming, the entire cam-motion system must be designed and produced. Families of parts, instead of requiring a different die for each size, sometimes need only one or two additional tools; the rest is accomplished with tool and feed adjustments.

Advantages with respect to tooling cost may also be realized through use of multiple-slide machines. The tooling used is generally simpler in construction than the average comparable die sets used in conventional presses. Piercing,

shearing, and forming units are of simple design and are relatively inexpensive to build.

Die details are mostly standard parts and can often be made at the plant where the machine is located. Forming units are fastened to the cam-driven rams by simple standard methods. The maintenance cost of this type of tooling is relatively low.

**Tool Adjustments.** Because the forming motions for a part are built into a fixed set of dies and cams, the initial setup time for equivalent parts is usually greater for a four-slide. However, the time required for tool adjustment and maintenance during production runs is less on four-slides.

**Combined Operations.** Four-slides perform tapping, welding, and other secondary operations that must be done separately in presswork. Four-slides can also interlock sections of a single part and assemble two or more parts.

**Heavy Press Operations.** Four-slides cannot do heavy coining or swaging, nor can they blank parts with a large number of die stations or high-tonnage requirements.

**Deep Drawing.** Draws exceeding 3.2 mm ( $1/8$  in.) are difficult to do on four-slides because of limitations on the lifter motions needed to clear the draws from the die.

**Operating Cost.** The per-piece cost of operating a multiple-slide machine is comparatively low. This is a direct result of a high rate of production. As many as 20,000 to 70,000 stampings can be made in a 16 hour shift on the fastest models, depending on the length of the stamping and the number of stampings produced per stroke.

## Factors in Selecting Multiple-Slide Machines

Multiple-slide machines can be applied to the production of numerous types of small parts. However, there are certain general limitations to observe in assigning work to this type of machine. These limitations are related to part size, design, and production volume.

**Size Limitations.** Dimensional specifications for stampings produced on multiple-slide machines must be held within the capabilities of the machines themselves. As indicated previously, these machines are applied to the production of relatively small stampings. The largest machines are capable of handling stock up to a maximum of 75 mm (3 in.) in width. The longest feed length possible is 320 mm ( $12\frac{1}{2}$  in.). Stock thicknesses up to 2.5 mm ( $3/32$  in.) can be handled. This range makes it possible for the largest machines to handle practically any thickness of stock used in automotive body or chassis stampings.

Smaller machines are limited in application to even smaller parts because the opening in the piercing head, which varies proportionately with press size, governs the width of material that may be processed. The smallest machine can

accommodate a maximum stock width of 20 mm ( $3/4$  in.) and a feed length of 75 mm (3 in.). Maximum stock thickness on smaller machines is 0.8 mm ( $1/32$  in.).

The stroke of the piercing-head ram varies from 9.5 mm ( $3/8$  in.) on the smallest machine to 19 mm ( $3/4$  in.) on the largest. The throw of the forming cams varies from 22 to 55 mm ( $7/8$  to 2 in.).

**Design Limitations.** The range of stampings that may be made on multiple-slide machines is somewhat limited in respect to part design. Basically, the use of these machines is limited to parts whose shapes can be achieved by shearing operations and pure bending operations. This confines the use of multiple-slide machines to types of operations such as piercing, notching, slitting, cutting and straight flanging, bending, and sizing. Extrusions are generally impractical because a solid stripper is used in the piercing head. An extrusion usually would prevent or interfere with the movement of the stamping to succeeding stations. Any forming in the piercing head must be done in a manner that will not hinder movement of the part.

Drawing or stretching operations are considered unfeasible both from the standpoint of tonnage requirements and the operational limits of the die setups that may be used. The press and tooling designs do not permit the use of air cushions or blankholding mechanisms required for these operations.

**Volume Requirement.** The volume requirement for a part is a further consideration in contemplating the use of a multiple-slide machine. Such a machine is a high-volume piece of equipment and as such can be used most profitably for high-volume operations. To avoid excessive downtime and loss of production in changeovers, parts not qualifying as high-production items should generally be produced by some other method.

## Tool Planning and Design

The principles followed in planning and designing tools for multiple-slide machines are similar to those used in layout of progressive dies for conventional presses. A strip development is made in which the operational elements are divided and set up in the most effective sequence. This indicates the die stations that must be built and their relative locations (Fig. 1).

**Sectional Construction.** In the construction of the dies, it is general practice to employ sectional construction. This is done to minimize maintenance problems and reduce downtime. Because a number of slides can be put into operation, the workload can be spread over a considerable distance. When numerous piercing or cutting operations are involved, several piercing heads may be employed. This permits spacing of the work to avoid crowding delicate punches together. It also reduces the necessity of building a long, heavy, and complicated progressive die. Further, versatility and changeability of the tooling setup is increased where multiple piercing heads are used. Making changes in any stage of the die is easier because it is unnecessary to remove and disassemble a large, complex progressive die.

**Component Strength.** Provisions should be made in designing multiple-slide dies for adequate strength and wearing qualities in all components. Punches, die inserts, and forming tools should be made of materials capable of withstanding rapid repetitive shock. Special hardened inserts should be supplied in all areas where tools are subject to exceptional wearing stresses. Rigid tool mountings are necessary to prevent deflection under load.

**Similarities to Presses.** Four-slide machines are similar to power presses in many ways. Both have feeding mechanisms that receive

Fig. 1 Hypothetical multislide application showing wide variety of functions that can be performed in production of complete stampings directly from coil stock

strip or wire material from a continuous coil. The material is fed into a die area in which press operations are performed in sequence at one or more stations. There, the similarities end.

Conventional power presses have tool motions in only one direction so that cam systems must be devised to form most complex parts. These systems are limited in what they can accomplish, and parts must be transferred from one machine or area to another for different operations. On the other hand, standard four-slides provide six or more forming slide motions within the forming area. These include four or more motions in the forming plane and two or more motions in a plane perpendicular to the forming plane.

A four-slide machine can perform most press operations within its strip-size capacity. Basic metal-processing operations that can be performed in a four-slide press section are: piercing, notching, coining, swaging, extruding, lancing, embossing, forming, beading, dimpling, stamping, and stippling. These press operations are completed before the forming operation.

**Other Operations.** Besides performing press operations prior to work the four-slide area, the machine can do other work before and after the forming steps—for instance, small brackets with three holes, one of which is threaded. All three holes are pierced, and one of them extruded, in the first die station in the press area of the four-slide. The extruded hole is then tapped in the press area.

Hose clamps can be formed from strip material that is first stamped to size in the press area. It is then cut off and formed around the center form so that the ends butt at the lugs. The part is pushed farther out on the center form into a welding station where the ends are pressed together and butt welded. By doing the welding independently of forming—so that forming and welding are performed concurrently—the production-cycle time is only that of the slower operation and not the total of the two.

In fabricating a small electrical part, a flat contact strip is dimpled and a hole pierced in the press area. After the strip has been formed on the center form, a threaded stud is fed from a magazine and dropped into the pierced hole. A staking head, located in the position of the right-side tool, finishes the cycle by staking the stud in place.

## Materials

The limitations on making parts in four-slide machines are usually related to materials properties, not machine capabilities. The mechanical properties of common strip materials that affect their suitability for four-slide production are tensile strength, yield strength, hardness, and ductility.

Obviously, tensile strength and hardness must be taken into account when planning for production by almost any mechanical method.

However, yield strength and ductility, by themselves, do not directly determine four-slide producibility. Instead, “relative formability,” in terms of bending characteristics and forming radii, is used.

Five families of strip materials commonly used in four-slide production are:

- Low-carbon, cold-rolled strip steels
- Spheroidize-annealed, cold-rolled spring steel
- Types 300 and 400 stainless spring steels
- Copper alloys
- Beryllium-copper alloys

**High-Formability Steels.** Low-carbon, cold-rolled strip steel and spheroidize-annealed spring steel are the most common high-formability materials used in four-slide production (see the article “Forming of Steel Strip in Multiple-Slide Machines” in this Volume). Cold-rolled strip steel (available in five tempers) is the basic ferrous material for four-slide parts other than springs. AISI 1075 spheroidize-annealed spring steel is the main material for spring parts, while AISI 1095 is used for spring parts in thinner sections. These two materials are hardened and tempered after forming to attain desired spring properties.

**Tempered Spring Steels.** The behavior of tempered spring steels in forming is difficult to predict. To control the mechanical properties, the strip mill should be required to fulfill two of three critical specifications: hardness, tensile strength, and minimum inside-bend radius without fracture. In addition, the allowable limits of reproducibility of mechanical properties should be established with the mill.

**Stainless Steels.** Type 302 is the most common stainless steel specified for four-slide parts. Other stainless steels that may be used (austenitic types, such as the 200 and 300 series) have mechanical properties similar to those of type 302. Series 400 stainless steels have properties similar to those of AISI 1075 spheroidize-annealed cold-rolled spring steel.

**Copper-alloy and beryllium-copper strip** are commonly formed on multiple-slide machines. There may be large differences in the hardness and tensile strengths of various alloys, even when they have roughly equivalent formability. It is thus important to evaluate relative formability in terms of bending characteristics and forming radii, even though a wide selection of mechanical properties may be obtained in nonferrous alloys. For example, beryllium-copper alloys are available in various treated conditions or mill-hardened conditions.

## Designing Four-Slide Parts

Forming of parts from metal strip on four-slide machines (Fig. 2) is a fast, low-cost production method. Often, parts made in multiple operations in power presses could be produced at much lower cost in four-slides. These machines

automatically produce metal parts from wire or strip by the combined action of a power-press section for stamping and cam-actuated sliding tools for forming. With a change in either the tools or the machine adjustments, a wide variety of forms and parts can be produced.

## Tolerances

**Thickness.** If close dimensional tolerances are expected, parts should be designed with mill dimensional standards in mind. Standard thickness tolerances for tempered and untempered cold-rolled carbon spring steel are the AISI mill standards. These standards cover approximately three-quarters of the four-slide parts that are made. Closer thickness tolerances on cold-rolled carbon spring steel are now available from specialty mills.

**Edges and Width.** Strip edges specified for four-slide strip parts are by far the most common in four-slide parts:

- A prepared edge of a specified contour (round, square, or beveled), which is produced when a very accurate width is required, or when the finish of the edge suitable for electroplating is required, or both
- An approximately square edge produced by slitting
- An approximately square edge produced by rolling or filing for the purpose of eliminating the slitting burr

Because most four-slide strip parts use the full width of the strip, AISI width tolerances on the raw strip material are also significant.

**Camber.** “Deviation of a side edge from a straight line” is the definition of camber. Standard AISI camber tolerances are 5 mm/m ( $1/2$  in./8 ft) for widths between 13 and 38 mm ( $1/2$  and  $1\frac{1}{2}$  in.), 2.5 mm/m ( $1/4$  in./8 ft) for widths over 38 mm ( $1\frac{1}{2}$  in.).

## Finishes

While many types of finishes can be produced in cold-rolled carbon steel strip, three are most commonly used:

- **Dull finish:** A finish without lustre, produced by rolling on rolls roughened by mechanical or chemical means. This finish is especially suitable for lacquer or paint adhesion and is beneficial in aiding drawing operations by reducing the contact friction between the die and the strip.
- **Regular bright finish:** A finish produced by rolling on rolls having a moderately smooth finish. It is suitable for many requirements but not generally applicable to plating.
- **Best bright finish:** Generally of high lustre produced by selective rolling practices, including the use of specially prepared rolls. This is the highest-quality finish produced and is particularly well-suited for electroplating.

Common finishes on hardened-and-tempered cold-rolled carbon spring steel include black, scaleless, bright, polished, and polished-and-colored (blue or straw) finishes.

### Design Hints

Design recommendations for producing metal parts in four-slides and power presses are similar to the extent that they are determined by mate-

rials characteristics or by part shape. However, there are also special differences.

The following design recommendations will give optimal part quality at maximum production speed.

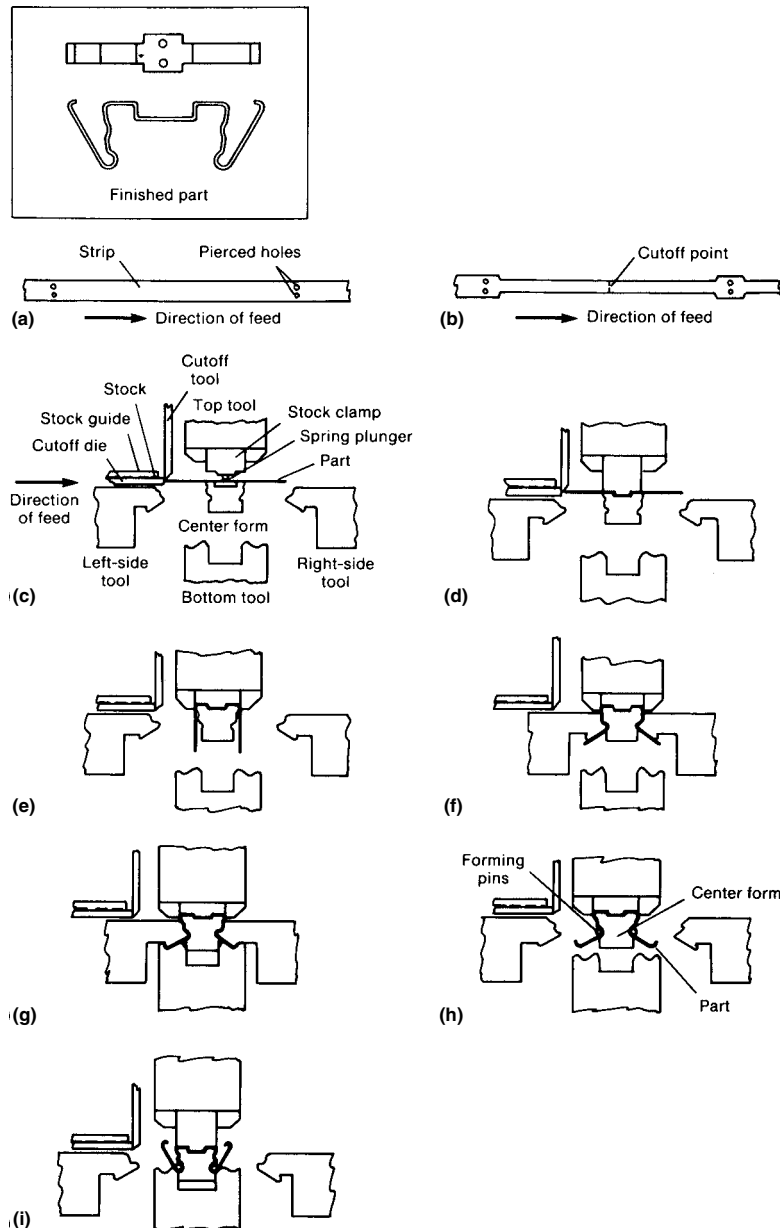

**External Contours.** Design recommendations for external contours are (see Fig. 3):

- Lugs or ears (Fig. 3a) should be formed with their bend lines at an angle equal to or greater than  $45^\circ$  to the rolling direction.

- Components requiring rounded ends (Fig. 3b) should have a radius equal to or greater than  $\frac{3}{4}W$ , except when otherwise indicated.
- A rounded end with a radius equal to  $\frac{1}{2}W$  may be used if a relief angle of  $10^\circ$  or greater at the point of tangency with the part edge is also used (Fig. 3c).
- Corners along the stock edge should be as near square as practical (Fig. 3d).
- The side that is to be free from burrs should be specified (Fig. 3e).
- All notches (Fig. 3f) should extend inside the stock edge at least  $1\frac{1}{2}T$ , but not less than 0.5 mm (0.020 in.).
- Tapers should be recessed at least  $1T$  from the edge of the part (Fig. 3g).
- Parts should have straight edges on the flat blanks wherever possible (Fig. 3h).
- To form a square corner, the minimum bend allowance should be  $1\frac{1}{2}T$  or  $R + \frac{1}{2}T$  if the corner is on a tapered end, and  $2T$  or  $R + T$  if on a square end (Fig. 3i).
- Relief slots for tabs, and short flanges whose edges are flush with the external blank outline, should have a depth of at least  $T$  plus the bend radius (Fig. 3j).
- When flanges extend over a portion of the part, a notch or circular hole should be used to eliminate tearing. Notch depth should be  $T$  plus bend radius (Fig. 3k). A hole should have a diameter of  $3T$ .

**Internal Contours.** Design recommendations for internal contours are (see Fig. 4):

- A radius of at least  $\frac{1}{2}T$  should be used at the intersections of all edges that do not lie along the stock edge and should be specified as maximum if radius is not critical (Fig. 4a).
- Punched (pierced) holes should have a diameter of at least  $1T$  (Fig. 4b), but not less than 0.76 mm (0.030 in.).
- The minimum distance from the edge of any round, punched hole to the blank edge should be at least  $1T$  (Fig. 4c), but not less than 0.76 mm (0.030 in.).
- Edges of adjacent punched holes should be a minimum of  $2T$  apart (Fig. 4d), but not less than 1.52 mm (0.060 in.).
- Extruded holes should have a minimum spacing of  $6T$  between their edges, and should be at least  $4T$  from the blank edge. Depth of the extrusion should be a maximum of 30% of its outside diameter (Fig. 4e).
- Holes should be spaced a minimum of  $1\frac{1}{2}T$  from bend tangent lines (Fig. 4f).
- Threaded screw or bolt holes should be at least  $1\frac{1}{2}$  times the screw diameter from the centerline of the hole to the edge of the part (Fig. 4g).
- Slots that are parallel to the bend should be a minimum of  $4T$  from bend tangent lines (Fig. 4h).
- Beads should be a maximum of  $2T$  high and have a minimum inner radius of  $1T$  (Fig. 4i).

**Fig. 2** Forming operations in a four-slide machine. (a) Power-press tools pierce two holes into strip material at first station. (b) Tools at next press station notch strip on both edges. (c) Notched-and-pierced strip is fed in from press area. As strip motion stops, stock clamp descends so that spring plunger holds strip against top of center form. (d) Cutoff tool cuts part off against cutoff die. At the same time, stock clamp descends farther to form workpiece into shaped cavity at top of center form. (e) As top tool descends, its right- and left-hand lobes bend ends of part straight down and hold them there. (f) Left- and right-side tools advance to form ends of part against shaped surfaces on sides of center form. (g) Bottom tool moves up to form tips of part against lower surfaces of left- and right-side tools. (h) Side and bottom tools retract. At the same time, two forming pins move out horizontally (toward the reader) outside the part. (i) Bottom tool advances again and bends ends of part upward around forming pins. Top and bottom tools withdraw vertically, while center form and forming pins withdraw horizontally into machine bed. Finished part falls out of forming area as next section of strip is fed in.

**Tabs and Slots.** The following recommendations are made for design of tabs and slots (see Fig. 5):

- Widths of tabs and slots should be a minimum of  $1\frac{1}{2}T$ , or 0.5 mm (0.020 in.). Their length should be a maximum of 5 times their width (Fig. 5a).
- Triangular tabs or slots should have minimum end radii of  $1T$  and should form included angles of  $60^\circ$  or more (Fig. 5b).
- Adjacent tabs or slots should be spaced at least  $2T$  or 0.76 mm (0.030 in.) apart (Fig. 5c).
- Internal slots should be at least  $1\frac{1}{2}T$  or 0.76 mm (0.030 in.) from the edge of the stock (Fig. 5d).

**Lugs, Bridges, and Curls.** Design recommendations for lugs, bridges, and curls are as follows (see Fig. 6):

- Lanced lugs should have tapered sides (Fig. 6a), except when otherwise indicated.

- A taper is not required when the lug margin is pierced with a clearance prior to forming (Fig. 6b).
- Bridges should have a maximum ratio of lanced length to bridge height of 4 to 1 (Fig. 6c).
- Curls should have inside diameters of  $2\frac{1}{2}$  to  $8T$  (Fig. 6d).

### Cutoff Methods

The four-slide machine is properly credited with built-in versatility in both its press and forming operations. The ability of the four-slide to produce small metal parts—complex or simple, to precise or commercial tolerances—in one machine cycle at high speeds is due also to the flexibility of the cutoff operation. Although the function of the cutoff is simply to separate continuous strip or wire into individual parts, the

ends of the parts can also be shaped and even formed, as needed, at the same time.

The various four-slide cutoff methods are illustrated in Fig. 7 as performed on a vertical-slide (verti-slide) machine. With the exception of the rear-motion cutoff in Fig. 7f, however, all the methods described here apply to any type of four-slide machine. In addition to those shown, there are many other techniques that are being applied to cutting off material in four-slides—and more will undoubtedly be developed in the future by ingenious tool engineers.

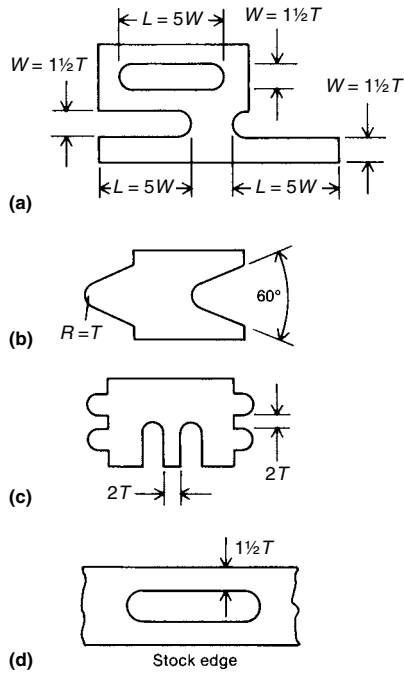

Fig. 4 Internal contours.  $T$ , stock thickness. See text for details.

*The Standard Strip Cutoff Method.* A standard cutoff head with a standard cam is usually used with conventional tooling. A straight cutoff (Fig. 7a) is made with a standard cutoff punch and standard die block.

*With Limited Space.* A straight cutoff can also be made with the standard cutoff die block, but with the cutoff punch or blade mounted on the side of the top forming tool (Fig. 7b). This

method is often used when the distance between cutoff die and center form is small.

**With Stationary Forming Arbor.** The standard cutoff attachment can be combined with a stationary forming arbor (Fig. 7c). The left-hand tail or leg remains in place until forming by the other forming slides has been completed.

**For Mating or Matching Cutoffs.** Using a standard cutoff attachment, the cutoff die block and cutoff blade can be designed to produce any desired mating or matching cutoff shapes (Fig. 7d).

**Double Cutoffs.** Unmatched cutoff shapes can be formed with a double cutoff die (Fig. 7e, left).

Another type of double cutoff (Fig. 7e, right) employs the standard cutoff attachment together with the bottom slide. This design usually is used only when the bottom tool is not required for forming operations. If the bottom tool is also needed for forming, special cams can be used.

**With Long Legs.** Wherever long legs must be formed down past a double cutoff die, a sliding die may be mounted in the standard cutoff attachment (Fig. 7f). This sliding die can be actuated by the left slide cam or by use of a specially designed cam motion. Again, note that independent end shapes are produced.

**Fig. 9** Multislide auxiliary equipment: rear auxiliary slide, rear-position knockout, and positive blankholder. (a) Rear auxiliary slide, for operations requiring motion in direction opposite die head. During die-head dwell, this unit allows a variety of operations, including shearing, forming, extruding, preforming, and lancing. (b) Rear-position knockout, employed to provide positive cam-actuated control, in place of die spring pads, for return of material flush with die surface. (c) Positive blankholder, used in the front forming-tool position to prevent slippage or bulging during cutoff and forming, and providing the ability to pilot and position the blank against the form

**Fig. 10** Multislide auxiliary equipment: front cutoff, rear cutoff, and split slide. (a) Front cutoff, for separating a blank from the strip prior to forming when scrap is not removed between blanks. Mounted between dies and forming position. Individual timing of cutoff permits separation at instant blank is held by forming tools or positive blankholder. (b) Rear cutoff, for separating blanks by removal of slugs of straight or shaped configurations. Small back-plate is furnished for cutoff-die mounting, allowing slug-removal-type parting when left-hand forming slide is used. (c) Split slide. A split front, right-hand, or rear slide can be furnished to operate in the standard slide opening, permitting tooling double movements for versatility in forming, locating, and assembly operations.

**Rear-Motion Cutoff.** The patented rear-motion cutoff (Fig. 7g) allows complete freedom of the verti-slide forming slides for more intricate forming operations.

After the strip has been fed all the way in over the center form, the rear-motion slide containing the cutoff die moves in under the strip. The cutoff punch moves down to cut the strip and then returns to its retracted position. The die then withdraws into the tooling plate, allowing the end of the cutoff piece to be formed downward.

**Wire Cutoffs.** A typical wire cutoff (Fig. 7h) uses standard cutoff components with regrinding for the particular wire diameter. A cutoff blade

on the side of the top tool may be used. A quill-type cutoff is also available (Fig. 7i).

**Multislide Auxiliary Equipment.** Four-slide forming machines accept wire or coil stock directly from a reel, straighten, feed, and cut off the required length. Figures 8, 9, and 10 illustrate auxiliary equipment used in typical operations performed by these machines.

# Wear and Lubrication of Sheet-Metal Forming Dies

SHEET METAL WORKING consists of blanking or cutting, forming of shallow parts, and deep drawing. Wear, lubrication, and selection of tool materials used for blanking dies and cutting tools are described in the article "Selection of Materials for Shearing, Blanking, and Piercing Tools" in this Volume. This article introduces the process factors that influence die wear and lubrication for metal forming operations such as bending, spinning, stretching, deep drawing, and ironing. Further details on these processes are provided in separate articles in the Section "Forming Processes for Sheet, Strip, and Plate" in this Volume.

In general, the amount of wear of dies during sheet metal forming is proportional to the distance the sheet metal slides over the die for a given pressure between the surfaces in contact. Thin annealed sheet metal exerts the least pressure and thus causes the least wear; thick hardened sheet metal causes the most rapid wear. However, the rate of wear for different combinations of die/sheet metal pair may vary considerably, depending on material surface characteristics, the speed of forming, and the type of lubrication. Die wear also depends on process characteristics. For example, high localized pressures develop on the tools that produce wrinkles, which then may produce prohibitively high rates of wear and galling in the ironing stage. Wear characteristics also differ for shallow forming and deep drawing, because these two operations impose different stress fields and wear profiles on the forming dies. These general factors are discussed in this article, with some recommendations concerning die materials selection based on the expected die lives. Further information on die materials selection is given in the articles "Selection of Materials for Press-Forming Dies" and "Selection of Materials for Deep-Drawing Dies" in this Volume.

## Wear in Shallow Forming Dies

To understand wear in shallow forming dies, it is essential to study the mechanics of the process based on the true shape of the parts to be drawn. For this purpose, six sample part shapes are included in Fig. 1, ranging from the simple

shapes, such as those of parts 1 and 2, to moderately severe shapes, such as those of parts 5 and 6.

Recommended die materials for these shapes range from plastics for low-quantity production of simple-to-moderate parts, up to the most wear-resistant (nitrided) tool steels for making severely formed parts. Parts of even greater severity, or those run in quantities larger than one million, may require dies or inserts of cemented carbide.

**Effect of Part Shape.** The tooling for parts 1 and 2 consists of a punch and an upper and lower die. Because there is little deformation of the sheet metal during forming of such simple parts, little or no sliding of the sheet over the lower die, and little movement over the punch, these components have very low wear rates.

Tooling for part 3 consists of a punch and lower die. In forming, the punch pushes the blank through the lower die, which results in sliding on the lower die, but there is little sliding on the

punch. Therefore, the punch generally has ten times the life of the lower die made from the same material. However, wear and galling are expected in the areas of moderate shrinkage of this part, particularly when the part is formed on these single-action dies.

Tooling for part 4 consists of a punch and upper and lower die. Without the upper die, excessive wrinkling would be expected at the shrink flanges. As in part 3, a less wear-resistant material is required for the punch and upper die than for the lower die due to greater sliding occurring on the lower die.

The tooling for parts 5 and 6 consists of a punch and lower die with no upper die required because these parts are produced by stretching rather than by shrinking of the metal along the constricted region. The metal envelops the punch with minimal sliding and consequently produces approximately ten times more wear on the lower die than on the punch. However, the same material can be used for both the punch and

Fig. 1 Parts classified into six classes based on severity of draw

lower die for part 5 because of the smaller part size and minor material cost. In the selection of die material for part 6, the critical locations are the wearing edges of the lower die. The body of the lower die could be made of cast iron with wearing edges of tool steel, and the punch could be of a material less wear resistant than tool steel, for example, low-cost alloy cast iron.

**Effect of Sheet Thickness.** Thick sheets of any metal will exert greater pressure on the dies than thin sheets of the same metal. Therefore, the effect of galling and wear increases as parts are made from thicker sheets, especially parts with shrink flanges. Consequently, for high-production dies working under severe wear conditions and for production of parts to close tolerances, it is often desirable to use an extremely wear-resistant material such as sintered carbide or nitrided D2 tool steel.

**Effect of Tolerance Requirements.** Tolerance requirements of the part affect the selection of tool material if the part is to be finished without redrawing. When the part is to be redrawn, the material used in the redrawing die is subjected to less wear than the die that performs the primary operation. A major factor in the choice between a wear-resistant material and a less costly and less wear-resistant material is the necessity for maintenance during the production run. If the production run is large and the tolerance requirements tight, costly wear-resistant materials or coated punches have to be considered.

**Effect of Sheet Metal.** Sheet stock of a higher hardness will usually wear dies more rapidly, but other factors, such as the presence of scale on the surface of unpickled hot rolled steels, are sometimes of greater importance. However, scales reduce galling, which, on tool materials, may be an even more serious condition than abrasive wear and can result in frequent interruptions for reconditioning the die.

Soft brass or aluminum stock causes less wear and galling than carbon steel, whereas stainless steels and heat-resistant alloys cause more wear and galling. Possible surface treatments include chromium plating of any hardened steel, hardening of alloy cast iron, and nitriding of tool steels such as A2 and D2.

**Effect of Lubrication.** In low- or medium-production runs, lubricants are often used; in zinc dies, they are a necessity. However, the most effective lubricants are difficult to apply and remove. Efficient application of lubricants is particularly difficult in high-production operations where presses are being fed automatically. In such operations, die materials that are costlier but more resistant to galling (for example, aluminum bronze, nitrided D2 tool steel, and sintered carbides) should be used.

**Prevention of Galling.** Galling is primarily due to large stretching of sheet metal, poor tool fitting, and rough finish on the surface of tools. For short or medium runs, surface-hardened hot rolled steel dies can be used that are less costly than tool steel dies. Tool steels are recommended for severe reductions or for forming metals that

show a greater tendency to gall, such as austenitic stainless steel.

If galling is encountered, the tool fit and thickness of the stock metal should be checked first to determine whether clearances are adequate. Ironing out wrinkles causes galling. Wrinkles can be prevented by redesign of the tools.

Surface nitriding of dies made from alloy steel or alloy tool steel such as A2 or D2 minimizes galling. However, in die steels containing no nitride-forming elements such as chromium or molybdenum, nitrided surfaces may spall on radii smaller than approximately 3 mm ( $1/8$  in.), and plated surfaces may spall on radii less than 6 mm ( $1/4$  in.). Hard chromium plating will usually eliminate galling of mild steel, alloy steel, and tool steel dies; however, to avoid cracking of the hard coating in operations involving high local pressures, hardened steels such as alloy or tool steels should be used as the substrate. Dirt, grit, and shot fragments on the sheet cause greater damage to nitrided and chromium-plated tools than to hardened tool steels; hard particles may cause minute spalling and small pits, especially at radii in areas of high forming pressure.

Galling is less likely if the die and stock materials are dissimilar in hardness, chemical composition, and surface characteristics (for example, aluminum bronze tools for forming carbon steel and stainless tools for aluminum parts).

Galling is also related to the thermal softening resistance of the die material. Galling and pickup are caused by the extremely high frictional heat generated between the die material and the steel being formed, which results in the softening of the die material and increased pickup.

On the basis of tests conducted by an automobile manufacturer, it was concluded that (Ref 1):

- Metal pickup on the faces of flanging dies is due to the frictional heat generated by two metals rubbing together under high pressure.
- Excessive heat is generated if the length of contact is longer than needed to form the flange.
- Correct die lubricants should be chosen. For example, when heavy gages are being formed, an extreme-pressure die lubricant should be used.

Wear and galling are less severe with soft stock material, such as aluminum and copper alloys, than with low-carbon steel; they are more severe with high-strength metals such as stainless steels and heat-resistant alloys.

**Die Wear and Die Life Studies.** The important factors influencing the wear and life of sheet-metal forming dies are the composition and hardness of the die material and the part, and the thickness, shape, and quantity of the parts to be formed. Effects of these factors are shown graphically in Fig. 2. The data for type 4140 steel show the effect of die hardness: Its die life increases approximately 800% when nitrided

(Fig. 2a). Effects of the tool material composition and hardness are seen in the forming of the label holder (Fig. 2b) and in the forming of the bushing (Fig. 2c). M4 and D7 at 65 HRC gave more than twice the die life of D2 (61 HRC) in flanging the shredder ring of 17-7 PH stainless steel shown in Fig. 2(d). The plots in Fig. 2(e) show the influence of die and stock material on wear of dies for making parts of similar shape. The wear rate gradually decreases for nitrided steels due to the wearing away of the outer layer (white layer).

## Wear in Deep-Drawing Dies

This section deals with the wear of material for dies to draw round and square cup-shaped metal parts in a press, primarily by conventional drawing in which each reduction is made in the same direction. Deep drawing is associated with extension and bending of the sheet over the punch nose, together with the gathering and compression of the sheet metal as it is drawn through the die. For economy of manufacture, the drawn part is always produced in the least number of steps using the least number of dies possible. Ironing is used almost universally in multioperation drawing and to increase uniformity of wall thickness. Each operation is designed for maximum practical reduction of the metal being drawn; the examples given in this section involve maximum reductions of approximately 35%.

The performance of a deep-drawing die is determined by the amount of wear or galling during a production run. Wear of a given die is determined largely by the material and thickness of the sheet steel, sharpness of die radii, lubrication, die design, and finish. The amount of wear on die radii can vary by as much as a factor of 20 between the sharpest and most liberal radii.

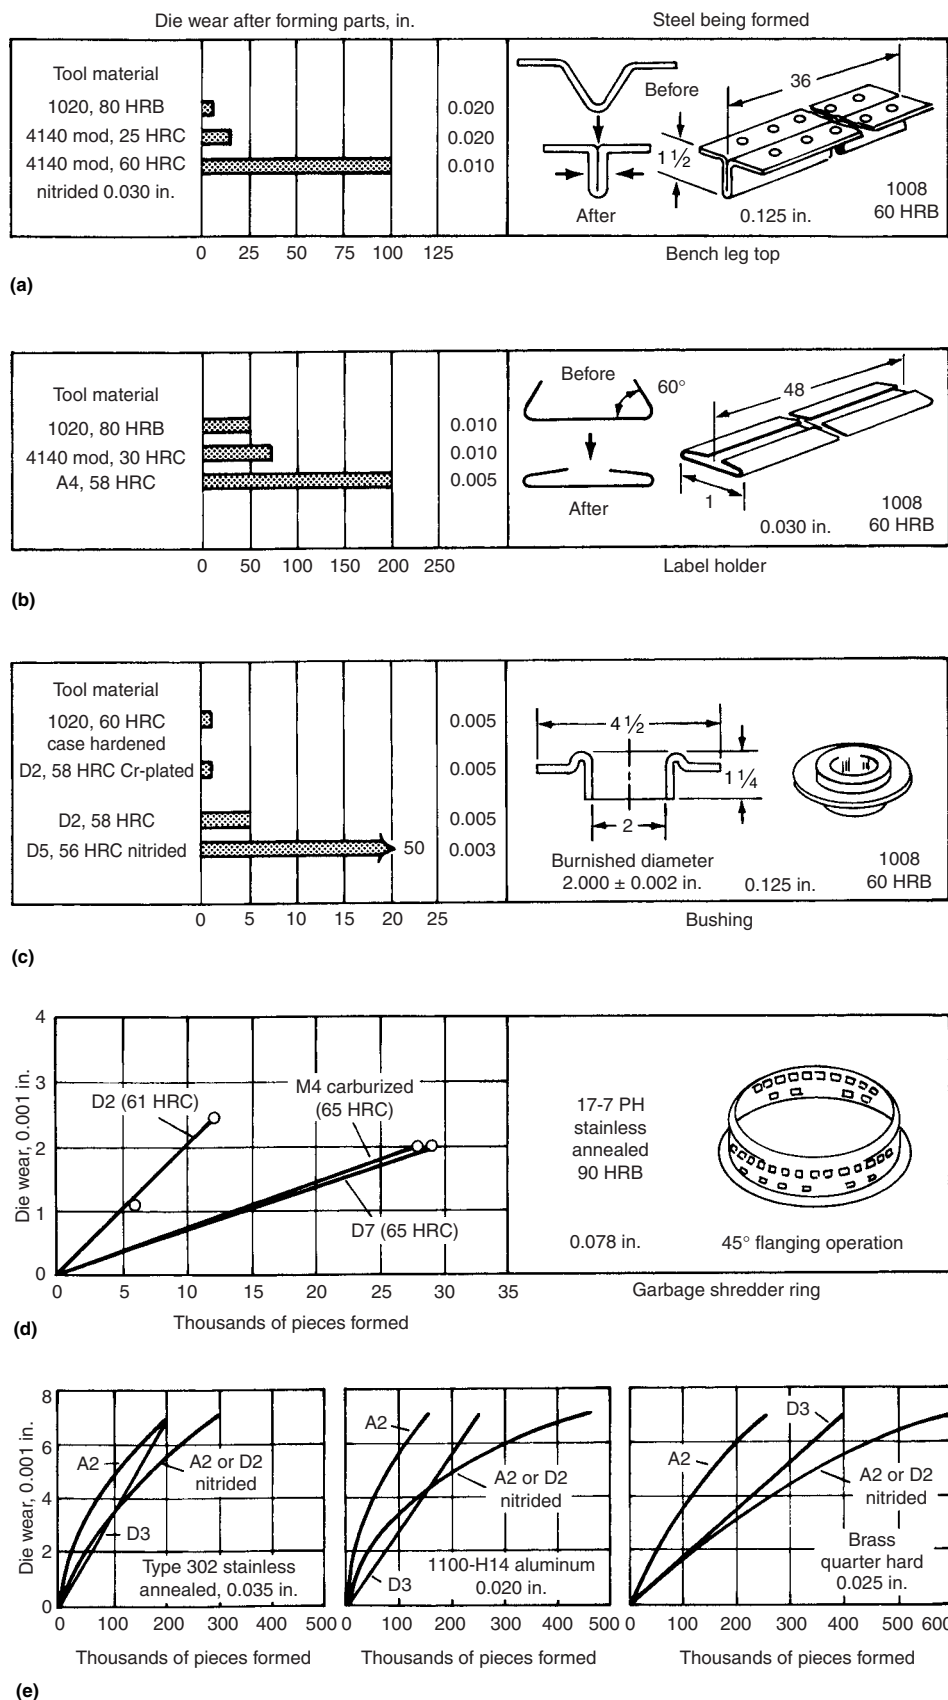

In drawing square cups, the formation of wrinkles at the corners accompanied by high localized pressures may produce prohibitively high rates of wear. Small corner radii will result in greater wear and shorter life of the dies.

High localized pressures caused by inaccurate fitting of dies during tryout, rough surface on the drawn sheet or on the working surfaces of the die, inadequate lubrication, and poor maintenance (stoning) of dies are typical of uneconomical practice.

**Effect of the Thickness of Sheet Metal.** In drawing thick sheets of a given metal, the pressure on the dies increases in proportion to the square of the sheet thickness. The die pressure is higher on the draw radius, and increasing sheet thickness will localize the wear in this high-pressure area without a similar effect on other surfaces of the die.

Thick stock will wrinkle less than thin stock; therefore, the pressures required to prevent wrinkling are less than those required for thin stock. However, heavy sheets are often drawn without a pressure pad. Therefore, the wear-resistance requirements for pressure pads used

**Fig. 2** Data on die wear and die life. The three plots in the bottom row relate to small instrument parts having a maximum area of 19 cm<sup>2</sup> (3 in.<sup>2</sup>). Source: Ref 1

on heavy stock are no greater than those for thin material. Alloy cast iron is often flame hardened for long runs and thick sheets; for small quantities and thin sheets, it may be used as-cast. For the mildest applications, unalloyed gray iron may be used.

**Prevention of Galling.** Common causes of galling are stretching sheet metal beyond practical limits, tool fitting with poor alignment or insufficient die clearance for the given sheet thickness, wrinkles, the use of galling-susceptible tool steel, and rough finish on the surface of tools.

Die materials to resist galling can be selected on the basis of their resistance to softening under heat. For example, T15 steel is the die material that has the highest resistance to softening and thus the best galling resistance; W1 steel has the poorest resistance to softening and galling.

For parts drawn of carbon steel or nonferrous alloy sheet, the die material can be selected without regard to galling; as a finishing operation, the punch and die should be either nitrided or chromium plated. If chromium- and molybdenum-containing tool steels such as A2, D2, D3, or D4 have been selected, the smoothly ground tools should be nitrided and polished or buffed after nitriding. Otherwise, the tools should be hardened to at least 60 HRC, smoothly finished on the wearing surfaces, hard chromium plated, and the plating polished or buffed. Punches should be plated to a thickness of 0.005 to 0.01 mm (0.0002 to 0.0004 in.). To prevent spalling or flaking of the plate, dies should not be plated more than 0.005 mm (0.0002 in.) thick.

When the parts are drawn from stainless steel or from high-nickel alloy steel, the drawing ring material with best resistance to galling is aluminum bronze. The second choice is either D2, D3, or D4 (smoothly ground, nitrided, and polished). The third choice is alloy cast iron (quenched and tempered to 400 to 420 HB).

Punch material is selected without regard to galling and is then chromium plated (as with die materials), unless cast iron is chosen.

Sintered carbide, which is only as efficient as the lubricants used, has proved economical for nonferrous alloys, carbon steel, and stainless steel in many long, continuous runs; however, galling will occur as soon as lubrication becomes faulty.

**Effect of Lubrication.** Correct lubrication of the parts being drawn is essential to reduce friction, wear, and galling. In fact, deep drawing is impossible without lubrication. In actual practice, die materials are selected after trials employing the production lubricants. If excessive wear or galling occurs, a better lubricant is usually applied. For extremely difficult draws, the best lubricants are usually applied at the outset. The effect of process conditions and lubrication is discussed in more detail in the next section, "Lubrication and Wear Process Conditions," in this article. Lubricants are discussed in detail in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

**Chromium Plating to Reduce Wear.** Chromium plating is used on tool steel draw rings to improve life. On punches, its primary function is to reduce the frictional forces and facilitate removal of the parts from the punch after the sidewalls have been ironed tight to the punch. Usually, chromium plating improves punch life somewhat less than it would be by the use of the next-best tool steel.

For successful performance of tools, chromium plating must always be deposited on a surface harder than 50 HRC, and the thickness of the coating should preferably be 0.005 to 0.01 mm (0.0002 to 0.0004 in.) and never less than 0.0025 mm (0.0001 in.). This gives the required hardness and reduction of friction without excessive spalling or chipping at corners. Chromium-plated dies should be heated to 150 to 205 °C (300 to 400 °F) for a minimum of 3 h immediately after plating to minimize the possibility of hydrogen embrittlement.

The main drawback is environmental, due to the poisonous nature of chromic acid. However, there are several suppliers that have developed the technique further with new additives and closed-circuit systems in order to take care of the waste products. The result is a more environmentally acceptable process as well as the possibility to produce crack-free coatings with superior corrosion-resistant behavior compared to conventional coatings (Ref 2). The price for this type of treatment will increase because of all the environmental issues.

The deposition temperature is approximately 50 °C (120 °F), and the hydrogen outgasing is normally performed at a temperature below or at approximately 200 °C (390 °F).

The deposition rate is typically between 5 and 20  $\mu\text{m/h}$  (195 and 785  $\mu\text{in./h}$ ), which results in cycle times of normally less than 1 to 2 h.

## Lubrication and Wear Process Conditions

Sheet metal working processes present a wide range of demands on lubricants, from the almost negligible to the most severe. In these processes, as in other non-steady-state processes, whatever lubricant is introduced at the beginning must suffice for the entire course of deformation. Therefore, lubricant breakdown, tool pickup, and scoring of the workpiece are of major concern. For a given process geometry, conditions generally become more severe with increasing sheet thickness.

An important point to note is that in most sheet metal working processes, yielding occurs in a predominantly tensile stress state. Typical conditions range from balanced biaxial tension (point 3 in Fig. 3), through plane-strain tension (point 4 in Fig. 3), to a combination of tension and compression (moving toward point 5 in Fig. 3). The compressive stress often originates in the geometry of the process, and, with the exception of ironing, die pressures remain low, well below the flow stress ( $\sigma_f$ ). This means that

contact is limited to asperities, and the Coulomb law of friction holds. Asperities yield at relatively low pressures when the substrate deforms in tension; thus, the real contact area and, with it, frictional stresses increase rapidly, resulting in a relatively high coefficient of friction. Correspondingly, friction plays an often decisive role in the success of the operation, which is measured by the absence of unacceptable necking or fracture of the workpiece. In contrast to bulk deformation, the magnitudes of pressures and forces, and of the effects exerted on them by friction, are of lesser concern.

In terms of lubrication during press forming, the primary function of lubrication is to prevent galling (tool material pickup). A secondary function is to reduce die wear through abrasive and chemical wear mechanisms. Light press forming of most metals requires only light mineral oil or soap lubrication to prevent die wear. More severe conditions, experienced when forming copper-, iron-, and nickel-base alloys, usually require liquid lubrication using either mineral oils with extreme-pressure additives (such as sulfur and chlorine) or zinc stearate soaps in order to prevent galling. Solid-film lubricants in the form of polyethylene, polyvinyl chloride, and polytetrafluoroethylene, which are applied to the workpiece as a powder, coating, or solid sheet, also give adequate protection against adhesive wear. Extreme conditions encountered when press forming iron- and nickel-base alloys require a phosphate-coated product and soap lubrication to prevent excessive die wear. Tin-coated steel, with additional liquid lubrication of mineral oil or emulsions to cool the die, has also been successful in preventing die pickup in severe press-forming applications. For more information on lubricants, see the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

**Bending.** In the basic process of bending, a part is deformed between a punch and a die. The

sheet gradually conforms to the punch nose, at low pressures and with very little sliding; friction effects are negligible here. Meanwhile, the sheet slides over the die radius, and a frictional force is generated. Because interface pressures are low—well below the flow stress of the workpiece material—contact is limited to asperities, and the coefficient of friction can be quite high. If the die/workpiece combination is prone to adhesion, pickup develops. If the workpiece is covered with an abrasive oxide, the die radius wears. In either case, the surface of the part is scored, die wear can become a problem, and lubrication is then essential.

Bending along a straight line is often performed with a steel punch and an elastomeric (polyurethane) pad. The elastomer imposes tensile stresses on the sheet, somewhat as in stretch forming. The stresses are transmitted by a frictional force that can be modeled by a coefficient of friction, the value of which depends on the surface condition of the blank and on the properties of the elastomer. Higher friction reduces springback.

Long lengths of shapes, such as tubes, corrugated sheet, and so on, are produced in large quantities by roll forming. Just as in shape rolling, the workpiece moves at a given constant speed while local velocities around the die profile vary, giving rise to relative sliding. Even though pressures are only fractions of those that occur in shape rolling, adhesive or abrasive wear, tool pickup, and workpiece scoring may be encountered. Lubrication is then helpful, although some friction must be maintained to prevent uncontrolled movement of the strip.

Bending of sections and tubes is widely practiced, and friction on the wiping elements of bending tools requires the use of lubricants. The difficulty of lubricating the inner surfaces of tubes calls for careful selection of the components. In radial bend-drawing of stainless steel, the wiper die and the flexible ball mandrel are made of

Fig. 3 Directions of principal stresses (a) and yield criteria with some typical stress states (b).  $\sigma_f$ , flow stress

aluminum bronze, and a viscous, compounded lubricant is applied that reduces mandrel tension and minimizes thinning on the tension side.

**Spinning** is an incremental forming process in which a circular blank is rotated and held between a male die (spinning block) and the tail stock in a machine tool resembling a lathe. The blank is pressed with a hand- or power-actuated tool so that it gradually conforms to the shape of the die (Fig. 4a). Localized pressures on the tool are high, and there is intensive sliding; thus, lubrication of the outer blank surface is essential.

In shear spinning, the wall of a previously formed cup or vessel is reduced. Strictly speaking, this is an incremental bulk deformation process with high surface pressures, and lubrication of the tool is essential. Friction problems are partially circumvented by the use of roller tools (Fig. 4b). Friction on the die (mandrel) hinders the free extension of the wall, but elastic springback helps to relieve the pressures and reduces friction.

In the presence of a liquid lubricant, lubrication is of the mixed-film type. A rougher surface is formed with a more viscous lubricant, higher spinning speeds, or larger rollers. However, it is essential that boundary agents be present, too. In shear spinning of steel, workpieces have been

coated with fat and with an emulsion applied during spinning to extract the generated heat.

**Stretching.** In pure stretching, the sheet is firmly clamped along its circumference while a male die (punch) deforms it (Fig. 5). The shape is developed entirely at the expense of sheet thickness. Therefore, necking and, finally, fracture of the sheet must eventually occur. The depth of draw before fracture and the location of the fracture point are functions of friction and of materials properties.

Thinning of the sheet takes place against frictional restraint over the punch surface. In the absence of friction, a condition that can be obtained by use of a hydraulic fluid as the punch, the sheet thins out gradually toward the apex, and fracture finally occurs in balanced biaxial tension. In the presence of friction, free thinning on the punch nose is hindered, the strain distribution becomes more localized (Fig. 5b), and the fracture point moves toward the die radius, where plane-strain conditions prevail. The total depth, obtainable before fracture sets in, diminishes. A higher strain-hardening exponent ( $n$ -value) has the same effect as reduced friction, whereas an increasing strain ratio ( $r$ ) value has the opposite effect.

At the start of deformation there is normal approach between punch and sheet, and, in the presence of a liquid lubricant, a squeeze film develops. Contact is made at the highest point; in stretching over a hemispherical punch, there is no sliding at this point (Fig. 6). Away from it, sliding distance and velocity increase at a rate proportional to the distance, if friction is low. With high friction, sliding is arrested. Interface pressures are low, because the membrane stress is typically on the order of 0.01 to 0.1 UTS (ultimate tensile strength). Nevertheless, surface deformation is substantial.

**Deep Drawing.** Tribological conditions vary greatly at various points of a partially drawn cup (Fig. 7). Conditions on the punch bottom

Fig. 4 The processes of (a) spinning and (b) shear spinning

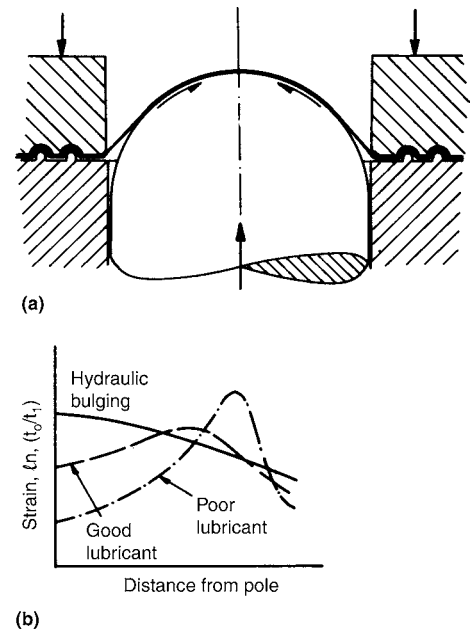

Fig. 5 Schematic illustration of (a) the limiting dome height test and (b) strain distributions obtained under different lubrication conditions

Fig. 6 Negative wedge developing in stretch drawing

Fig. 7 Zones of differing lubrication conditions in deep drawing (see text for identification)

(zone 1) are the same as in stretching, except that friction around the radius (zone 2) limits the transmission of stresses, and interface pressures may drop close to zero. The sheet roughness is virtually unchanged. On the punch radius ( $R_p$ ), the stresses are higher, some relative sliding takes place, and the lubricant thins out.

Between the punch flank and the partially drawn cup (zone 3), the lubricant is trapped in a squeeze film, whereas it is drawn in under favorable conditions at the point of transition (zone 4). Pressures are low and can easily drop to zero if elastic springback occurs, or if the clearance is large enough to allow the cup to separate from the punch in the early stages of drawing. The surface roughens as in free deformation, in combined tension/compression, and the presence of a lubricant makes little difference.

Around the die radius ( $R_d$ ) (zone 5), pressures are somewhat higher—by analogy to a frictionless pulley, on the order of  $(t/R_d)$  UTS. Because  $R_d = 5t$  to  $8t$ , the pressure is approximately 0.2 UTS, which is still quite a small value. Sliding conditions are, however, severe. The speed is equal to the drawing speed, and the surface, deformed by circumferential compression and bending and unbending, becomes progressively rougher. There is danger of exposing virgin surfaces, and tool pickup is observed only on the die radius, if at all.

Fig. 8 Combined stretching/drawing of an irregular part with (a) draw bead and (b) edge bead

Fig. 9 Draw stresses developed in drawing of 0.9 mm (0.035 in.) steel sheet with a low-viscosity rust-prevention oil ( $\mu = 0.15$ , solid lines) and with a high-viscosity drawing oil ( $\mu = 0.035$ , broken lines).  $\mu$ , coefficient of friction

In the blankholder zone (zone 6), pressures are low—typically 0.002 to 0.02 UTS. A liquid lubricant is trapped by a squeeze-film effect. Thickening of the flange creates a wedge that contributes to lubrication by hydrodynamic action. In materials of planar anisotropy, there is more thickening in the low  $r$ -value direction, and thus the film is thicker in the high  $r$ -value direction. The surface roughens under the imposed tensile/compressive stresses at a higher rate than in pure tension, but roughness is still proportional to strain if the effects of anisotropy are considered.

When the clearance is such that ironing takes place at the rim, the surface becomes smoother, and roughness depends on the thickness and nature of the lubricant film.

A sheet of directional surface finish or metallurgical structure exhibits visible parabolic markings, which are accentuated in the presence of a liquid lubricant.

**Combined Stretching and Drawing.** Many parts are made by pressworking processes that incorporate elements of both stretching and drawing. The shapes of these parts range from simple rectangular containers to complex, irregular shapes of automotive components. At the corners, the stress and strain states are similar to those observed in deep drawing, and the wall height is built up by circumferential compression, for which the high  $r$ -value direction in a sheet with planar anisotropy is favorable. At the sides, the wall is formed by draw-in of the sheet in plane strain, and a high  $n$ -value is favorable. The base of the part is frequently domed (Fig. 8), and therefore, contact between punch and sheet is localized and a large area of the sheet is unsupported, resulting in puckering. Another problem is springback, which distorts the shape of gently curving parts.

Higher pressure on a flat blankholder increases the resistance to draw-in. However, more positive control is obtained with draw beads (Fig. 8a), which function by repeated bending and unbending of the sheet. In principle, they are

effective even without friction. The restraining force increases with decreasing bead radius, and a round-cornered square is more effective than a fully radiused bead. Draw beads are usually made as inserts and are more readily adjustable than edge beads (Fig. 8b). Friction on the bend radii, on the blankholder surface, and on the die radius are important contributors to the draw force (Fig. 9). With proper lubrication, the draw beads change the strain history in various parts of the drawn part and through this contribute to an increased limiting depth. Draw beads present the dangers of pickup and sheet damage. Draw beads made of polyurethane are less effective but minimize scoring.

Combined stretching and drawing offers a wide scope for differential lubrication. When the drawing component dominates, use of a dry punch and a lubricated blankholder zone (combined with a high  $r$ -value) results in the deepest parts. Overall lubrication provides only a small improvement when stretching is dominant; a high  $n$ -value is much more helpful. Punch friction is still important, though. High friction minimizes thinning, whereas low friction promotes deformation in a curved bottom and thus minimizes springback. The punch radius must be lubricated sufficiently to allow plastic deformation over the entire base (for which the stress must exceed the initial flow stress or yield strength) without exceeding the strength of the wall (for which stresses must remain below the UTS).

**Ironing and Necking.** In ironing, the wall of a cup is reduced over its entire height without materially changing its inner diameter (Fig. 10). Problems in ironing are similar to those encountered in tube drawing on a bar, except that the part is shorter and the lubricant finds relatively easy access to the inside. Interface pressures are on the order of  $\sigma_f$ , and sliding velocity on the die is equal to the punch velocity. Sliding velocities on the punch are much lower.

Ironing can be applied simultaneously with drawing but is generally a separate operation. Long employed for the manufacture of cartridge cases and similar products, it has acquired great significance with the spread of two-piece beverage cans that are drawn and then ironed, usually in three stages, to a much-reduced wall thickness. Substantial expansion of the surface demands a lubricant capable of following surface extension. Friction transfers stresses to the punch and increases the attainable reduction (Fig. 11, Ref 3).

Theoretically, very high reductions can be taken if friction on the punch is high. This conclusion is also confirmed in practice. Reductions close to 60% are feasible with a lubricated punch, and reductions up to 70% can be attained with a dry punch, provided that the die angle is small enough. Even though the frictional force on the die increases with a decrease in half angle, so does the frictional force on the punch. Reductions in excess of 90% are possible in a single pass when the die half angle is less than  $6^\circ$ .

Fig. 10 Ironing of a cup (half arrows indicate directions of frictional stresses acting on cup)

A neutral point develops inside the ironing zone, and the material can emerge at a speed higher than that of the punch. A limit is set by the difficulty of stripping the ironed can, especially

when it is a thin-wall can, as in two-piece canmaking. To prevent collapse of the can, the punch is usually smooth and is lubricated together with the die.

Processes of great practical importance are necking (nosing) and expansion of can or tube ends. The maximum necking ratio (ratio of diameters before and after necking) is limited by development of circumferential folds, or by axial collapse or upsetting of the wall. The latter two failure modes are especially sensitive to both friction and die angle. For a given angle, the tube may actually become longer with lower friction, as shown in (Ref 4). The maximum necking ratio is greater for a  $30^\circ$  than for a  $60^\circ$  included die angle.

**Fig. 11** Effect of lubrication on reduction obtainable in ironing with dies of different half angles. Source: Ref 3

# Selection and Use of Lubricants in Forming of Sheet Metal

LUBRICANTS AND LUBRICATION are relatively low-cost components of a metal-forming system, yet lubricants are important and often indispensable for efficient forming of quality parts. The primary function of lubrication in press forming is to prevent galling (tool material pickup). A secondary function is to reduce die wear through abrasive and chemical wear mechanisms, as briefly discussed in the article "Wear and Lubrication of Sheet-Metal Forming Dies."

This article provides an overview of the interfacial interactions with a lubricant film between a die and metal, lubricant mechanisms, chemistry, qualification testing, application methods, and property test methods. Much of the discussion is relevant to metal-forming operations in general, although it is targeted at sheet-metal forming operations. The final sections deal with lubricant selection as influenced by the metal to be formed and particular sheet-metal forming operations. Some aspects of microbiology and toxicity also are discussed, as are the increasingly important health and economic implications of laws and regulations dealing with metalworking lubrication. Economic and environmental factors are a driver in the development tool coatings that reduce or eliminate the need for lubricants.

## Surfaces

In general, the specific characteristics of the surfaces of both the sheet and the dies make up the environment in which sheet metal lubrication is considered. As such they provide the boundaries between which the lubricant must operate. These surfaces are complex. The chemistry of the surface is not the same as the bulk chemistry of the sheet or tools. The lubricant interacts with an oxide layer of varying complexity; various contaminants may infiltrate the oxide layer (oil, gases, acids, rust preventives, and so forth); and the surface may be carburized or decarburized, nitrided or subjected to some other surface treatment, or coated with a polymer or phosphate. Many other surface chemistry variations are possible. Furthermore, the surface may have residual compressive or tensile stresses from

prior processing. The fine structure of the metal surface may also vary with prior history and be quite different from that of the bulk material. The surface roughness also varies in many geometrically significant ways. Interposed between these nonhomogeneous surfaces is a lubricating film that may be quite complex in structure, activity, and wetting ability.

The complexity of the lubricant/metal interface fundamentally affects the lubricant performance by preventing galling or wear of the tooling, as well as tearing, scratching, or imperfect forming to desired dimensions of the sheet metal.

## Lubrication Mechanisms

In sheet-metal forming, several different lubrication regimes have been identified. More than one of these regimes may occur during sheet-metal forming. Indeed, a single regime often cannot be effective in providing the necessary film integrity between tool and workpiece. The specific regimes that are operational depend on the severity, temperature, and geometry of the deformation mode. Detailed information on lubricating mechanisms is available in Ref 1 and 2.

**Thick-film (hydrodynamic) lubrication** (Fig. 1a) is the occurrence of a thick film of lubricant between tool and workpiece that completely prevents metal-to-metal contact. In hydrodynamic lubrication, a thick lubricant

film is generated by the tangential and normal relative motion between two surfaces. In this regime, the bulk properties of the lubricant (viscosity) and the mechanical system operating during deformation create the necessary conditions. The effectiveness of such lubrication depends directly on relative speed and lubricant viscosity. For very slow contacts, a thick film is not likely to develop unless hydrostatic lubrication (i.e., an externally pressurized lubricant) is introduced into the lubricant film.

Lubricant film thickness is important in hydrodynamic lubrication to prevent possible solid-to-solid contact. It is usually determined from solutions of the flow continuity equation, which calculates the lubricant pressure for a known film thickness. Charts and computer software are available for determining the lubricant film thickness for many common geometrical configurations. Lubricant film thickness increases with the sum of the two surface velocities ( $v$ ), lubricant dynamic viscosity ( $\eta$ ), and bearing size, and decreases with load.

**Thin-Film (Quasi-Hydrodynamic) Lubrication.** The film between tool and workpiece is thinner, and some metal-to-metal contact takes place (Fig. 1b). In this case, the load is shared by the hydrodynamic (or fluid) pressure and the asperity contact pressure. For this reason, thin-film lubrication is sometimes referred to as mixed lubrication, or partial hydrodynamic lubrication. It occurs in bar and wire drawing and perhaps less frequently in sheet-metal forming. Nonetheless, in most press working, relative sliding speeds are

**Fig. 1** Three lubrication regimes experienced in sheet metal forming. (a) Thick-film lubrication. (b) Thin-film lubrication. (c) Boundary lubrication

too low and the process geometry is not favorable enough to maintain a full fluid film (Ref 1). This is why solid-film lubricants are often preferred to maintain a full fluid film. Most liquid lubricants operate in the mixed-film regime.

**Boundary Lubrication.** Physical adherence of the lubricant to the surface occurs, and relatively thin lubricant films may be effective (Fig. 1c). Dependence on viscosity is lower, and chemisorption (chemical adherence of the lubricant to the metal surface) becomes more important. The adherence and strength of the adsorbed film governs lubrication effectiveness.

**Extreme-Pressure Lubrication.** The metal surfaces are chemically altered because of reaction between the lubricant and the metal surface. These reactions often involve sulfur, chlorine, or phosphorus present in the lubricant reacting with the metal surface to form sulfides, chlorides, or phosphides. These compounds may be very complex in composition. Lubrication is provided because the films formed are low in strength and shear readily under deformation.

## Solid Lubricants

When difficult press work operations require film strength in excess of that which is possible with solutions and emulsions, a paste, suspension, or coating may prove to be the best lubricant choice. Pastes may be oil- or water-base, pigmented or nonpigmented. Pigments include talc, mica, or similar inactive but effective high-strength barrier film formers. Sodium or potassium soaps are used widely in the production of all types of pastes. Buildup of lubricant in the tooling and the necessary cleaning of workpieces are the main drawbacks of pastes.

Suspensions are used frequently to provide a desired barrier film. Fine particles of a solid, such as graphite, Teflon (E.I. duPont de Nemours, Wilmington, DE), or clay, are suspended in a fluid carrier. Surfactants of an appropriate chemistry are generally required in order to provide suspension stability. Stability and lubricant buildup on dies are potential problems during use. Coatings applied to sheet metal surfaces—most often at the sheet or strip finish mill—have been used alone or as undercoatings to lubricants applied at the press. Water-soluble polymers, phosphate conversion coatings, soap solutions, and organic resins (either with or without other additives) are used. Generally, coatings are applied by dipping or spraying and then are heated to promote film formation and adhesion. Control of deposit thickness and chemistry, as well as removal, may be operating problems during production.

In solid-film lubrication, separation of tool and workpiece occurs by interposing a solid film. These solids act to provide a hydrodynamic film as long as they maintain surface integrity. The mechanism of solid-film lubrication is essentially the same as that of thick-film lubrication (Fig. 1a), except that the lubricant is a solid substance.

Solid-film lubricants include polymers such as polyethylene (PE), polyvinylchloride (PVC), and polytetrafluoroethylene (PTFE), which are applied to the workpiece as a powder, coating, or solid sheet and also give adequate protection against adhesive wear. Extreme conditions encountered when press forming iron- and nickel-base alloys require a phosphate-coated product and soap lubrication to prevent excessive die wear. Tin-coated steel, with additional liquid lubrication of mineral oil or emulsions to cool the die, has also been successful in preventing die pickup in severe press-forming applications. Other types include molybdenum disulfide, graphite, sodium carbonate, Teflon, nylon, and other solids in a carrier.

Solid films are often preferred so that the film thickness can be controlled by application rather than by process conditions alone. Such films also offer the possibility of differential or selective lubrication.

**Dry Soaps.** Even though dry soaps may be modeled as viscous substances and have speed-dependent actions, their method of application is a dry-film type. For good adhesion, the surface must be clean, preferably freshly pickled. Soap-film thickness is controlled by the concentration and/or temperature of the aqueous solution. Subsequently, the water is driven off by heating in ovens. These coatings are related to the soaps used in wire drawing and are based on mixed soaps of selected fatty acids. Borax is often added as a filler and presumably to improve attachment to the surface. Sensitivity to moisture can be reduced by replacing borax with a polymer. The melting point is adjusted according to the severity of operation to avoid melting.

Soaps have been most successful on steel. On stainless steel they are adequate only with coated tools. They are seldom used on nonferrous metals because the slightly alkaline coating etches the metal and develops stiffer, higher-melting soaps on storage. The coating does not protect against corrosion or rough handling, but it has the advantage of water solubility and does not seriously interfere with welding.

Soaps applied to conversion-coated surfaces ensure a high lubricating power that is needed only in severe ironing or in drawing of stainless steel. Their use may be justified also when the part has to be phosphated anyway. Waxes have excellent lubricating properties for all metals but have to be applied from and removed by organic solvents.

**Polymer Coatings.** Numerous polymers are useful in bearing applications, but for metal-working purposes only thermoplastic polymers of the appropriate glass-transition temperature are of interest (Table 1):

- Polyethylene is readily available in sheet form and possesses substantial elongation (100 to 300%). In combination with mineral oil, sheets 2.5 to 7.5  $\mu\text{m}$  (98 to 295  $\mu\text{in.}$ ) thick provide excellent lubrication. Polypropylene has similar properties.

- Polytetrafluoroethylene (PTFE) sheets have limited ductility, but well-adhering films of controlled thickness and good extendability can be deposited from a trichlorotrifluoroethylene dispersion of telomers (which have aliphatic end chains grafted onto the PTFE). Sputtering is possible too.
- Polyvinylchloride (PVC) is available both in sheet form and as a deposited coating.
- Polymethylmethacrylate (PMMA), and acrylics in general, have the advantage that they are readily deposited from either solvent solutions or emulsions, and they can be modified to endow them with boundary-lubrication properties.
- Acetal resins contain the linkage  $-\text{CH}_2\text{O}-\text{CH}_2\text{O}-$  and have found some limited application.
- Polyimides formed with aromatic radicals have outstanding temperature stability.

Most polymers are used as coatings. Among the earliest were methacrylate copolymers deposited from trichloroethylene solutions or from aqueous dispersions. The value of PTFE, especially in the baked-on form, was discovered early on and PTFE has potential application in drawing of aluminum hollowware. For better adhesion, these films are often deposited onto a ceramic substrate, fired onto the sheet surface. The pressworking of strip precoated in a special facility, often at the rolling mill, has received much attention. These coatings ensure clean shop conditions and protect the part during handling.

Polymer coatings impart greatly increased stretchability, approaching that obtained in hydraulic bulging. In deep drawing and incidental ironing the forces are substantially reduced, thus increasing the limiting draw ratio (LDR). An important requirement is that the film should not wrinkle or stick to the dies. To avoid cracking and peeling in tensile regions, the polymer must have high elongation and good adhesion to the sheet. Coatings that soften at low temperatures may be damaged when worked on high-speed mechanical presses.

Under mild conditions, coated sheets can be formed dry. In more severe situations, additional lubrication is needed. Lubricants applied at the pressworking plant must be chosen for compatibility. For example, PVC is attacked by chlorine-containing lubricants. In general, water-base lubricants, mainly waxes, are preferred; often they can be left on the finished part. It is necessary, however, to test them for possible delayed damage to the coating on the formed part.

**Layer Lattice Solid Lubricants.** Layer lattice coating is a term used to describe films of atoms with a hexagonal crystal structure (where spacing between basal planes is defined as the *c*-spacing, and spacing between the atoms within the basal planes is defined as the *a*-spacing). Compounds with a high *c/a* ratio have very an-isotropic shear properties with preferred shear parallel to the basal planes or perpendicular

to the *c*-axis of the crystal structure. For example, dichalcogenides (disulfides, diselenides, and ditellurides) of molybdenum and tungsten have this structure. With the possible exception of tungsten diselenide, all of these compounds have lubricating properties, even in a vacuum.

**Layer-lattice compounds** have been used mostly in pastes, greases, and high-viscosity oils designed for use on heavy-gage material or in pressing at elevated temperatures. Some bonded films can survive severe ironing. For demanding applications, particularly for metals that do not react readily with lubricants, dry films deposited from liquid or volatile carriers have been used. Proprietary or locally made lubricants often contain a variety of other ingredients, sometimes as tackifiers or parting agents and at other times with little clear justification. In general, however, a common problem with layer-lattice compounds and nonorganic fillers is the relative difficulty of their removal.

**Metal Coatings.** Metal coatings find their most extensive use on sheet products. Most applications involve steel, but the principles are universal. Under mild conditions, tin alone can facilitate drawing.

For corrosion resistance of car bodies, galvanized (zinc-coated) sheet is used. LDR is

improved in deep drawing, and higher blank-holder forces are needed in press forming. Cracking or flaking of the film may occur, particularly in the compressive zone, and die pickup can be a problem. Polished, hard-chromium coated tools give best results.

**Coatings.** Soft coatings are used extensively for lubrication or lowered coefficient of friction. In addition, hard coatings are also used for good wear resistance with the accompanying low coefficient of friction. Such coatings are primarily carbides, nitrides, oxides, or borides of simple elements or alloys deposited by physical vapor deposition (PVD) and chemical vapor deposition (CVD) techniques. These include relatively simple compositions such as TiN, TiC, and Al<sub>2</sub>O<sub>3</sub>; more complex compositions such as (TiAl)N and Ti(C,N); and multilayer coatings, such as TiC/Al<sub>2</sub>O<sub>3</sub>/TiN.

A group of PVD coatings that frequently are used in applications where wear resistance in combination with low friction is required are diamondlike carbide coatings (DLC). These coatings typically are doped with metals, e.g., Cr or metal carbides such as WC. The beneficial low-friction property of DLC coatings makes them increasingly interesting also for different tooling applications such as dry metal forming

and dry machining of soft materials such as aluminum. Carbon coatings containing metal (WC/C) and the combination of hard coatings (TiN, TiCN, TiAlN) with WC/C reduce the erosion tendency, and in some cases, they even permit a lubricant-free manufacturing process.

## Fluid Lubricants

The three principal fluids (water, oil, and synthetic) that make up the primary ingredients of sheet-metal forming lubricants are combined with additives to achieve the desired operating characteristics. Table 2 lists the relative effectiveness of four types of lubricants for various functions. Some of the more important additives used to achieve particular lubricant characteristics are described in the section "Additives" in this article. However, it is first desirable to discuss the various possible forms of the lubricant (solutions, emulsions, and pastes). Additional information is also described in the section "Lubricant Types."

**Solutions.** A fluid in which all components are mutually soluble is a solution. All of the fluids mentioned may form solutions, with soluble additives selected for their mutual solubility with the fluid and for their effect on properties. It is common practice in the field to call water-base solutions synthetic fluids or lubricants; oil-base solutions are called compounded oils; synthetic fluids that are compounded are also called synthetic lubricants. This shop language can be misleading if not understood.

Aqueous solutions have the highest cooling capacity and tend to promote operational cleanliness. Resistance to biological contamination is superior except for the possible formation of mold. Corrosion protection and operator skin inflammation (dermatitis) are potential problems.

Compounded oils tend to have superior thick-film lubrication properties and resistance to biological attack. They also provide good corrosion protection. On the other hand, workpiece cleanliness, cleaning of parts, welding, and higher end-use cost may be problems.

Synthetic compounded lubricants have superior high-temperature properties, but much higher costs restrict their use in forming operations.

**Emulsions.** A mixture in which one immiscible fluid is suspended in another in the form of droplets is called an emulsion. The continuous phase in most sheet-metal forming operations is water. The suspended phase is oil or a synthetic fluid and may contain solid lubricants such as graphite, mica, or sodium carbonate. The continuous phase also may contain additives. In all cases, however, stabilization of an emulsion requires one or more surface-active agents (surfactants), finely divided solids, or special mixing techniques.

Surfactants such as fatty acids exist in an emulsion with the acid radical of the molecule preferentially soluble in the water, and the

**Table 1 Thermoplastic polymers and their transition temperatures**

		370 (700)	

organic, fatty portion of the molecule dissolved in the oil phase. In this way, the surfactant acts as a glue across the water/oil interface, thereby improving stability. This phenomenon is illustrated in Fig. 2, which shows the emulsifier action of three different emulsion systems as droplets of oil are suspended in water. In Fig. 2(a), the surface-active ingredients sodium cetyl sulfate and cholesterol are close-packed at the oil/water interface, thus producing an excellent tight emulsion. In Fig. 2(b), the sodium cetyl sulfate and oleyl alcohol interact at the interface to form a poor, or loose, emulsion. The effect of the surfactants is minimal in reducing the surface free energy of the oil droplets; therefore, emulsion stability is poor. Figure 2(c) illustrates an intermediate case, which may be desirable in some cases because relatively large oil droplets occur, rather than the small droplets that are present in a tight emulsion. The presence of larger oil droplets may benefit the performance of the lubricating film.

A special case of emulsion is used frequently in sheet-metal forming to take advantage of the cooling properties of water and the lubricity of suspended oil. The particle size of the suspended oil is small enough that the lubricant concentrate, even when water is added, remains clear rather than turning white or off-white, as is typically the case with an emulsion.

Emulsions generally are relatively easy to remove from parts and equipment. They provide superior cooling but may be more susceptible to biological contamination and have less-effective lubricating and corrosion-preventive properties than other lubricants.

## Lubricant Chemistry

Metalworking lubricant formulations commonly consist of a petroleum-oil carrier (or base)

that is compounded with additives of various types. The oil-additive combination is often emulsified in water. Lubricants that are based on synthetic oils, rather than petroleum oils, are also used. Some metalworking lubricants contain no oil at all, but consist of friction-modifying additives and corrosion inhibitors dispersed or solubilized in water.

Tool life and part integrity are directly affected by lubricant choice. The mechanical and chemical properties of the lubricant are influenced by operating conditions (temperature, pressure, geometry), as well as by the surface characteristics of the tool and workpiece. Further, the lubricant chemistry has important implications with respect to cleaning costs, welding integrity, corrosion of equipment and parts, recycling and disposal costs, and operator health and safety.

### Carriers (Bases)

The chemical components of the lubricant consist of a combination of a carrier (base) with various additives. Different lubricants have different viscosities: fluids, solids, pastes, or gels may be used. Fluids are currently the most widely used lubricants for sheet-metal forming. Lubricating fluids are based on mineral oils or solvents, synthetic fluids, water, or some combination of these.

**Oils.** Petroleum oils are naturally occurring materials that are refined from crude oil by fractional distillation processes such as distillation, hydrotreating, solvent extraction, molecular sieving, and dewaxing to give desired properties. Petroleum oils are commonly called mineral oils. The mineral oils or solvents are used as a base for lubricants. Important physical attributes include viscosity, color, and odor, as well as chemical attributes, such as degree of saturation and freedom from undesirable elements such as sulfur.

Petroleum oils are generally classified as paraffinic, naphthenic, or aromatic. Paraffinic oils are classified further as either linear paraffins or isoparaffins. The molecular species associated with each classification is illustrated in Fig. 3. The oils are generally immune to biological

**Fig. 2** Three types of emulsions seen in sheet metal forming lubricants. (a) Excellent (tight) emulsion. (b) Poor (loose) emulsion. (c) Intermediate case with poor emulsion stability

**Table 2** Relative effectiveness of different types of lubricants for various functions

Function	Relative effectiveness(a)			
	Compounded oil	Oil-in-water emulsion	Semisynthetic solution	Synthetic solution
Provide lubrication at high pressure (boundary lubrication)	1	2	3	4
Reduce heat from plastic deformation (heat transfer)	5	2	2	1
Provide cushion between workpiece and die to reduce adhesion and pickup (film thickness)	1	2	3	4
Reduce friction between die and workpiece and, thus, heat	1	2	2	1
Reduce wear and galling between tool and workpiece (chemical surface activity)	4	3	2	1
Flushing action to prevent buildup of scale and dirt (fluid flow)	5	4	3	2
Protect surface characteristics; nonstaining	5	2	2	1
Minimize processing costs, welding, cleaning, and painting	5	2	2	1
Minimize environmental effect, air contamination, and water recovery	5	2	2	1

(a) 1, most effective; 5, least effective. Source: After Ref 3

attack, are readily recycled, have inherent lubricity and good metal-wetting characteristics, and afford some metal corrosion protection. The viscosity of selected oil or solvents varies over a wide range, as does the molecular structure.

Linear paraffins consist of straight-chain hydrocarbons, whereas isoparaffins consist of branched-chain hydrocarbons. Naphthenic oils consist of hydrocarbons that contain five- or six-member ring structures that may be unsaturated, but not aromatic. Aromatic oils consist of hydrocarbons that contain totally unsaturated six-member rings known as either benzene or aromatic rings. Petroleum oils generally consist of a mixture of paraffinic, naphthenic, and aromatic molecules and are classified by the species that predominates. For example, a petroleum oil consisting of 70% naphthenic molecules is called naphthenic.

The different classes of oils have different properties. Linear paraffins, for example, have high resistance to oxidative degradation, whereas the naphthenic oils tend to be more reactive oils and are more easily emulsified.

**Synthetic Fluids.** Synthetic hydrocarbons, such as polyisobutylenes and polyalphaolefins, with a specific molecular structure are used widely as lubricants. Although less commonly used and more expensive than petroleum oils, synthetic fluids are used as bases for metalworking lubricants in cases where their tailored properties can more than make up for their higher cost. Examples of some synthetic fluids are illustrated in Fig. 4. These fluids, which are based on synthesized hydrocarbons (polyalphaolefins) and polybutane derivatives, are often referred to as synthetic oils.

Fig. 3 Examples of molecular species contained in petroleum oils

The polyalphaolefins are similar to refined base oils in characteristics but have superior resistance to oxidation. Polyalphaolefins, while not employed as commonly in metalworking operations as are polyglycols and polyisobutylenes, have properties that make them useful for some operations. They can be used over a wide temperature range, and they produce less hydrocarbon emissions than petroleum oils at similar viscosities. They are highly resistant to oxidative and thermal degradation.

The polyglycols, polyolesters, and dibasic acid esters have superior high-temperature stability; however, they are not as readily combined with desired additives for corrosion protection or metalworking ability. Polyglycols are often used in metal removal lubricant formulations. These materials are prepared through polymerization of ethylene oxide and propylene oxide in either random or block fashion. The terminal groups can be either alkyl groups or hydrogen. Properties are controlled by molecular weight, nature of terminal groups, and the ratio of ethylene oxide to propylene oxide. For example, high molecular weight versions have high viscosities. Polyglycols with high ratios of ethylene oxide to propylene oxide tend to be water soluble,

Fig. 4 Examples of molecular structures of four classes of synthetic fluids

whereas those with low ratios tend to be water insoluble. The ratio can be adjusted such that the polyglycol is water soluble at room temperature, but water insoluble at elevated temperatures. This property can be very useful in formulating solutions that are clear in the circulating system but will separate polyglycol and the additive package from solution at the hot tool-workpiece interface.

Polyisobutylenes can be made in a wide range of viscosities by controlling molecular weight. They have a unique property of depolymerizing at high temperatures. This makes them useful as rolling and drawing oils for ferrous and non-ferrous forming operations where subsequent annealing would produce staining if petroleum oil forming lubricants were used.

Multiply-alkylated cyclopentanes are a new class of synthetic hydrocarbons that are promising in terms of future formulations. Their properties can be varied over a wide range by varying the number and nature of alkyl groups. They have excellent pour points and viscosity indexes, as well as exceptionally low volatility. A number of synthetic fluid categories beyond those discussed previously also exist, but have limited use as base oils in metalworking operations.

**Water.** Because of the rising cost of refined mineral oil as well as the intrinsically high cost of synthetic fluids, water as the base fluid for sheet metal lubrication has become more widely used. New technology methods use various forms of water-base fluids (solutions, emulsions, gels, and pastes).

Of particular importance in the performance of water-base lubricants is the superior heat transfer capability of water. The sheet-metal forming operation generates heat due to friction and metal deformation; water is the most efficient fluid for dissipating this heat.

**Viscosity of Carriers.** Viscosity is a measure of the resistance of a fluid to flow and is a very important lubricant property. Kinematic viscosity, which represents the resistance of a fluid to flow under gravity, as measured by the ASTM D 445 test, is the preferred method for describing the viscosity of lubricants. In ASTM D 445, a fixed volume of lubricant is allowed to flow through a calibrated orifice that is held at constant temperature. The kinematic viscosity is calculated by multiplying the flow time in seconds by the calibration constant of the viscometer. The correct SI unit of kinematic viscosity is  $\text{mm}^2/\text{s}$ . A centistoke, which is equivalent to  $1 \text{ mm}^2/\text{s}$ , is also commonly used. The standard temperatures for measuring viscosity are  $40^\circ\text{C}$  ( $104^\circ\text{F}$ ) and  $100^\circ\text{C}$  ( $212^\circ\text{F}$ ). The viscosity of fluids decreases as temperature increases. Viscosity index is an empirical, dimensionless number that indicates the rate at which lubricants change kinematic viscosity with temperature. The higher the viscosity index of a lubricant, the less rapidly its viscosity changes with temperature.

In metal forming operations, viscosity is a major factor in determining the lubricant film that separates the tool from the workpiece and

thus is critical in controlling friction and wear. In metal removal operations, optimum lubricant viscosity must be estimated for a particular operation. Factors to be considered in estimating the optimum viscosity of a metal removal fluid include the capability of the lubricant to penetrate and remain in the contact zone, the durability of the lubricant film, the desired rate of spreading, and the cooling capability.

### Additives (Ref 4–6)

Although uncompounded fluids may successfully serve as lubricants in light sheet-metal forming, other processing requirements such as cleaning and corrosion protection may be satisfied only by the addition of chemical additives. Further, in more difficult forming operations, the base oil does not totally separate the tool from the workpiece. Thus, additives must be used to provide necessary film characteristics for lubrication. In water-base metalworking lubricants, special materials are employed to disperse or solubilize the oil-additive package in water.

Film-strength additives adsorb on tool-workpiece surfaces and prevent direct metal-to-metal contact and the subsequent welding of asperities and destruction of the workpiece surface. These additives are often called boundary additives, load-bearing additives, oiliness additives, or friction modifiers. Film-strength additives consist of materials with a polar head and a hydrocarbon tail generally containing 10 or more carbon atoms. Compounds that function as film-strength additives include fatty acids, esters, alcohols, amides, amines, and alkyl acid phosphates. Higher-viscosity lubricants give thicker lubricant films and, therefore, less tool-workpiece surface contact and lower friction in metalworking operations.

**Emulsifiers**, often called surfactants, are materials that have portions within the same molecule that are hydrophilic, or compatible with water, and lipophilic, or compatible with oil. The hydrophile-lipophile balance (HLB) of an emulsifier is a measure of its tendency to be more compatible with water or oil. The HLB scale runs from 0 to more than 30, with oil compatibility decreasing and water compatibility increasing at higher numbers. Emulsifiers with HLB values higher than 13 form clear solutions in water.

Emulsifiers are used to promote stable emulsions and, in some cases, the cleanability of oils. Anionic and nonionic surfactants are the preferred emulsifiers. Typical nonionic emulsifiers are complex esters, fatty acids plus alcohols, monoglycerides, and ethoxylated alcohols. Some anionic surfactants used are soaps of long-chain fatty acids, alkyl aromatic sulfonates, and phosphate esters. Soaps are the most widely used anionic emulsifiers, but they may react with hard water to form compounds that can be difficult to remove from die or part surfaces.

Because emulsifiers have portions of their molecules compatible with water and other portions compatible with oil, they tend to con-

centrate at the oil-water interface in oil-water mixtures, reduce oil-water interfacial tension, and thereby promote emulsification. The emulsification process is that technique in which oil globules that are larger than colloidal size are dispersed in water. Petroleum oils, animal and vegetable oils, synthetic oils, and waxes each have an HLB value at which they form the most stable emulsion. This is known as the “required HLB” of the material to be emulsified. Required HLB values are different for different materials. For example, the required HLB to emulsify a paraffinic petroleum oil is 10, whereas the required HLB to emulsify castor oil is 14. An emulsifier or emulsifier combination that has the same HLB as that required of the material to be emulsified is chosen if the most stable emulsion is desired.

Emulsifiers are classified as cationic, anionic, amphoteric, and nonionic. The most common cationic emulsifiers are long carbon chain quaternary ammonium halides. Anionic emulsifiers include alkali metal and amine soaps of long carbon chain fatty acids, and long carbon chain sulfates or sulfonates. Examples of amphoteric emulsifiers include long-chain amino acids and alkyl betaines. Examples of nonionic emulsifiers include ethoxylated alcohols, ethoxylated fatty acids, and ethoxylated sorbitol. The most commonly employed emulsifiers in metalworking lubricants are the nonionic and anionic types.

**Extreme-pressure (EP) additives** are used when the fluid alone does not prevent excessive tool-part friction and wear. The most commonly employed EP additives are compounds containing sulfur, chlorine, phosphorus, or some combination of two or more of these elements. Extreme pressure additives function by forming a reaction layer triggered by the high temperatures reached at the tool-workpiece interface in ferrous metalworking operations. For example, phosphorus-containing compounds produce iron phosphates, iron pyrophosphates, or iron phosphides, depending on the nature of the compound. Sulfur-containing compounds produce iron sulfide, whereas chlorine-containing compounds produce iron chloride. These chemical compounds are relatively weakly bonded and fracture and slide easily under the conditions of forming, providing a separating layer between tool and workpiece. Instability of the lubricant, as well as staining and corrosion, may be encountered during use. Cleaning and welding may also be adversely affected.

Examples of EP additives include sulfurized triglycerides, chlorinated hydrocarbons, chlorinated esters, phosphate esters, and alkyl acid phosphates. Closely associated with EP additives are so-called “antiwear” additives containing the same elements. A commonly used class of antiwear additives are the zinc dialkyl dithiophosphates.

A new class of EP additives, called passive extreme pressure (PEP) additives, was introduced in the 1980s–90s. They function by adsorbing a film of carbonate particles at the tool-workpiece interface in metalworking

operations. These films have low shear strengths and high melting points. They reduce friction and minimize metal transfer from the workpiece to the tool. Passive extreme pressure additives do not contain phosphorus, sulfur, or chlorine but are synergistic with sulfur-containing EP additives. They offer advantages over conventional EP additives in that they are less corrosive, are more easily disposed of after use, are low foaming, and are easily cleaned from the workpiece surface. They can be used with both ferrous and nonferrous metals.

**Thickeners** are used to alter the flow characteristics (viscosity) of the fluid lubricant. Flow characteristics are influenced by temperature and pressure and affect lubricant performance. Organo-clays, polymers, natural gums, and metal hydroxides are used to vary flow properties. Stability of the lubricant system and buildup on tooling may cause operating problems.

**Antimisting agents** are used to reduce the incidence of airborne particles of the metalworking lubricant. Particularly in the case of solvents or low-viscosity oils, air mists may form that are detrimental to health and may also cause equipment-operating problems. To reduce mist formation, small quantities of polymers such as acrylates or polybutanes are added. When contacted with polymer, the lubricant base builds larger particles so that they do not readily form a mist.

**Passivators** are added to reduce the activity of the metal surface in order to prevent staining, particularly of nonferrous metals. Organic amines, sulfur, and nitrogen-containing compounds are used as passivators. Frequently, a so-called passivator is used in conjunction with corrosion-prevention additives such as complex borates to improve the performance of each.

**Antifoaming agents** may be required to prevent foam formation if the lubricant is recirculated. Foaming is undesirable because it may interfere with reservoir cleanup and fluid flow or complicate fluid application. Lubricant foaming can even lead to lubricant starvation if excessive amounts of the lubricant mass are in the form of foam.

Foam is created when air is injected into the lubricant either through spraying at the metalworking operation or through circulation of the lubricant through the lubricant handling system. Nearly all water-base metalworking lubricants contain emulsifiers, which not only lower oil-water interfacial tension but also lower the surface tension of the lubricant compared with water. The surfactants concentrate at the air-fluid interface and form an elastic film that expands, but does not rupture, as air is introduced.

In order to prevent foam formation, the surface free energy of the film must be reduced. This may be achieved with a wide variety of additives, including silicones, amides, glycols, and fine particles of selected solids such as silica. Small additions of these chemical agents, called antifoams or defoamers, can drastically reduce or eliminate foams. The concentration of these agents needed for effective foam control is low;

however, monitoring concentration to maintain control may be a problem.

A good defoamer must have the right combination of dispersibility and surface tension. It should spread throughout the system without dissolving in it, and it should spread over the foam surfaces. When this happens, the defoamer acts at the gas-fluid interface to collapse the elastic film of the fluid, thereby allowing it to release the air and drain. Silicones are very effective defoamers. Their major drawback is that if the workpiece is to be coated or painted in a subsequent operation, adhesion may be adversely affected. Nonsilicone defoamers include long-chain alcohols, certain triglycerides, and water-insoluble polyglycols.

**Suspended Solid Lubricants.** Solid lubricants are often suspended in oil- or water-base fluids for extremely heavy-duty forming of sheet metal. These solids are graphite, carbonates, mica, polytetrafluoroethylene (Teflon), nylon, metal powders, metal oxides, metal halides, and molybdenum disulfide. The solids are generally in the form of very finely divided powders held in suspension by either mechanical agitation or emulsifiers, or a combination of both. The oil or water carrier often functions solely to coat the die and workpiece in a uniform fashion, and the solid itself functions as a lubricant.

Solid lubricants have the general property of being easily sheared at the tool-workpiece interface. However, buildup on tooling and cleaning of workpieces are potential problems during operations with these suspended-solid lubricants. Suspended solids are not generally used in metal-removal lubricants, although some types of PEP agents are colloidal suspensions.

**Corrosion inhibitors** are frequently added to both water- and oil-base lubricants to provide parts protection during processing and storage. Parts corrosion may be a particularly difficult problem when water-base lubricants are used; however, sulfonates, carboxylates, borates, and phosphonates have been successful in alleviating corrosion. In oil-base lubricants, organic amines and sulfonates, as well as phosphates and unsaturated fatty acids, have been used successfully.

Prior to the 1980s, a commonly used and very effective corrosion inhibitor was sodium nitrite. In the mid-1970s, it was discovered that nitrosamines, which are carcinogenic, were contained in many commercial metalworking formulations. The nitrosamines were found to arise through a reaction between sodium nitrite and secondary amines, particularly diethanolamine. Therefore, much work has been done to find suitable replacements for sodium nitrite.

Corrosion inhibitors, particularly with water-base lubricants for ferrous metals, protect the workpiece during and after processing. A number of types of compounds have been developed for the prevention of ferrous metal corrosion in modern metalworking lubricants. These include amine-borates, amine carboxylates, amine alkyl acid phosphates, and sulfonates. None of these materials forms nitrosamines and are therefore more acceptable.

Corrosion inhibitors for nonferrous metals are important in some metalworking operations. Benzotriazole is an effective corrosion inhibitor for copper or brass. Cobalt corrosion inhibitors, such as tolyltriazole, are used to prevent cobalt leaching in those operations employing cobalt-cemented tungsten carbide tools. Toluyltriazole has been used successfully to protect copper sheet from staining and corrosion.

**Oxidation inhibitors**, also called anti-oxidants, are formulated into metalworking lubricants to minimize oxidative degradation of the lubricant into acidic products that tend to form sludge and corrode metal surfaces. Oxidative degradation involves molecules containing unpaired electrons called free radicals. These radicals are transformed into degradation products while transforming other lubricant molecules into more free radicals in a chain reaction. Small concentrations of oxidation inhibitors functioning as free radical scavengers intercept the unpaired electrons and break the chain. Oxidation inhibitors are not normally used at levels above 0.5%. Commonly used oxidation inhibitors include hindered phenols, such as butylated hydroxytoluene and butylated hydroxy anisole, and secondary aromatic amines, such as phenyl naphthyl amine. Because the rate of oxidation occurs much more rapidly at elevated temperatures, oxidation inhibitors are especially useful for hot metalworking operations, such as the hot rolling of either ferrous or nonferrous metals.

**Antimicrobial agents** are materials designed to inhibit the growth of bacteria, fungi, and yeast in metalworking lubricants. All water-base metalworking lubricants are vulnerable to attack by one or more of these agents; even oil-base lubricants containing small amounts of water as a contaminant can be degraded by microbes. Thus, antimicrobial agents may be required in order to prevent the growth of anaerobic or aerobic bacteria.

Bacteria frequently cause various operating problems in emulsions or solutions that contain oil and water, and attack of metalworking lubricants by bacteria leads to one or more of the following:

- Buildup of acidic materials
- Buildup of lubricant on workpieces
- Corrosion of machinery and tools
- Objectionable odors
- Destruction of additives
- Loss of emulsion stability

Growth of fungi also can lead to slimy material coating the machinery and tools, as well as the clogging of pumps and filters.

Microbes can generally be controlled at acceptable levels through use of antimicrobial agents known as biocides and fungicides. Care in handling as well as monitoring are important if biocides are to be used safely and effectively. Bacteria, fungi, and yeast are often monitored on a regular basis through commercially available simple culture techniques, and when counts reach a certain level, there is cause for alarm. In

solutions formulated with various chemical components, bacteria will generally not be the problem; rather, formation of mold can cause malfunction of pumps and filters, and buildup on tooling and workpiece surfaces. It may also alter the solution chemistry. Biocides are not required when lubricant application does not involve repeated use or recirculation of the fluid.

Standard practice often calls for the addition of two different biocides to the metalworking lubricant at regular intervals in an alternating fashion, in order to guard against microbes developing an immunity to one of them, resulting in an uncontrolled infestation. Although many types of biocides exist, two of the most common are phenolic materials and formaldehyde-release agents. Phenolic materials, such as 2,4,5-trichlorophenol, destroy bacteria directly. Materials such as 1,3-di(hydroxy-methyl)-5,5-dimethyl-2,4-dioximidazole, upon being added to water-base metalworking lubricants, release formaldehyde slowly to keep bacteria in check. Materials such as 2,2-dibromo-3-nitropropionamide are useful for controlling bacteria, fungi, and yeast.

There are over 50 commercially available antimicrobial agents. In choosing the proper one, parameters such as the required concentration, effect on emulsion stability, and regulations concerning discharge into waste streams must be taken into account. Finally, antimicrobial agents are designed to destroy living organisms. They all display some degree of toxicity toward humans and should be handled with caution.

## Lubricant Types (Ref 4)

Four commonly used types of metalworking lubricants are illustrated in Fig. 5. Straight metalworking oils, often simply called straight oils, are given this term because they are not mixed with water prior to use. Emulsions are mixtures of either simple or compounded oils with water, stabilized by the use of emulsifiers. Emulsion droplets are similar in size to, or larger than, the wavelength of visible light; hence, emulsions appear milky white. Microemulsions can be similar to emulsions in composition, but, through emulsifier choice, have oil droplet diameters that are much smaller than the wavelength of visible light and therefore appear transparent. Micellar solutions are similar to microemulsions, except that they contain no oil.

Petroleum oils, as defined previously, are naturally occurring materials that are refined through processes that separate the crude substances into various molecular fractions and remove impurities. In some cases, they are hydrogenated or subjected to reforming catalysts but are not otherwise chemically altered. The chemical reaction of smaller molecules produces the larger molecules of synthetic fluids, such as poly- $\alpha$ -olefins and polyisobutylenes. In metalworking lubricants, the term *synthetic* is often used to describe either transparent micellar solutions (Fig. 5) or true solutions containing no

petroleum oils. Unfortunately, this dual definition for synthetic lubricant has led to confusion. It should be obvious that if the definition of synthetic lubricant is one that contains a preponderance of man-made materials, then the straight oil, emulsion, or microemulsion of Fig. 5 is, strictly speaking, synthetic, if the base oil is a synthetic fluid such as poly- $\alpha$ -olefin, rather than a petroleum oil.

**Straight oils** are generally petroleum oil fractions that are normally formulated with either film-strength additives or EP additives, or a combination of both. They generally provide excellent friction reduction and workpiece surface finish, good corrosion protection, and a long service life. Straight oils containing certain EP additives will stain nonferrous metals, such as copper, and are commonly referred to as staining oils. The major disadvantage of straight oils is their poor capability for heat removal, compared with water. In addition, straight oils with low flash points, coupled with the high temperatures often encountered in metalworking operations, can create fire hazards. Straight oils are commonly used in metalworking operations where lubrication is a major factor and cooling is a minor factor. Examples of such operations include low-to-moderate-speed metal-removal operations where accuracy, tolerance, and workpiece finish are important, and metal forming operations such as aluminum foil rolling where strip surface quality is highly important.

**Emulsions.** In commonly used metalworking emulsions, oil globules are finely dispersed in water, and this oil-water combination is employed as a lubricant-coolant. In these types of emulsions, oil is said to be the dispersed phase, and water, the continuous phase. Oil-in-water

mixtures are thermodynamically unstable; that is, their state of lowest free energy is total separation. Because of this, oil tends to separate, and emulsifiers are added to stabilize the emulsion. Emulsifiers concentrate at the oil-water interface and inhibit coalescence of oil globules, as illustrated in Fig. 6. The structural formula of sodium oleate, an anionic emulsifier, is shown in Fig. 6(a). A simplified "straight pin" is depicted in Fig. 6(b). An oil-in-water emulsion stabilized by sodium oleate is shown in Fig. 6(c). The hydrocarbon chain of sodium oleate is compatible with the oil globules and penetrates them. The carboxylate head of sodium oleate is compatible with water and lies at the surface of the oil droplet penetrating into the water phase. Because the carboxylate head carries a negative charge, the surface of each oil droplet is negatively charged, and because like charges repel, the oil droplets tend to stay dispersed. Because the state of lowest free energy of the emulsion is still total separation, the emulsion is said to be kinetically stabilized.

Emulsions can vary in stability over a wide range, depending on the nature of the oil phase and the nature and concentration of the emulsifier package. Emulsion oil globule size can vary from approximately 0.2  $\mu\text{m}$  (8  $\mu\text{in.}$ ) to as high as 10  $\mu\text{m}$  (400  $\mu\text{in.}$ ) or more. Therefore, emulsions appear as off-white to white opaque solutions. The globule sizes within a given emulsion are polydispersed; that is, they vary over some distribution. Stable emulsions have smaller average globule size distributions than do unstable ones.

A major factor in lubricating with emulsions is the availability of the oil phase to lubricate. Two factors control oil availability: the emulsion

stability and the concentration of oil in the emulsion, which is often called "percent oil." In general, the less stable the emulsion and the higher the percent oil, the greater is the availability of oil for lubrication. Unfortunately, the less stable an emulsion is, the higher is the tendency for stability to change, sometimes rapidly, over time. This can lead to undesirable instability in some metalworking operations, such as rolling. Also, as the percent oil in an emulsion increases, cooling capability decreases. Therefore, the stability and percent oil in an emulsion must be carefully balanced to satisfy the lubrication and heat-removal needs of a particular metalworking operation.

The fact that emulsions are kinetically, rather than thermodynamically, stable leads to other factors in their behavior. One of these is called the emulsion "batch life." New emulsions are generally the most stable and have the least oil available for lubrication. Metalworking operations are often not optimal when a new emulsion batch is introduced. Over time, as debris is generated in the emulsion, providing nucleation sites for oil globule coalescence, and as emulsifiers are depleted, the emulsion becomes less stable and performs at its best. At yet a later time, the emulsion becomes so degraded and unstable as to be rendered useless and is discarded. A new batch is introduced, and the process repeats itself. In general, emulsions that are initially less stable have shorter batch lives. A second factor is the care that must be taken upon introducing foreign substances into the emulsion. For example, introduction of a biocide to combat a microbial infestation or contamination by acids or bases can greatly affect emulsion stability and therefore the consistency of the metalworking operation.

Metalworking lubricant emulsions are often complex mixtures of emulsifiers, film-strength additives, oxidation inhibitors, corrosion inhibitors, and coupling agents. Coupling agents are generally lower molecular weight diols and triols that aid in the initial emulsification. Emulsions can also contain various mixtures of EP additives. The formulated oil mixture is called the concentrate and is added to water with agitation to form the emulsion. The quality of the water is extremely important. Distilled or deionized water should be used whenever possible. Metalworking emulsions generally operate at levels between 5 and 10% oil.

Metalworking emulsions are maintained in a variety of ways. The percent oil is determined by breaking the emulsion in a graduated bottle with an acid or salt solution, and it is maintained by adding new concentrate during the life of the batch. Nonemulsifiable tramp oils (those that have leaked into the metalworking lubricant) are skimmed off, and the emulsion is subjected to continuous filtration to remove fine debris. In the case of metal-removal fluids, chips are often removed by mechanical means. Microbe levels are monitored and controlled by the addition of appropriate antimicrobial agents at prescribed intervals. Emulsions have good lubricating and

Fig. 5 Commonly used metalworking lubricants

heat-removal qualities and are used widely in most metal removal operations and many metal forming operations.

**Microemulsions** are clear-to-translucent solutions containing water; a hydrophobic liquid, that is, an oil phase; and one or more emulsifiers, which are often referred to as surfactants and cosurfactants. Microemulsions in which water is the continuous phase and oil is the dispersed phase are called oil-in-water microemulsions and are the type generally used as metalworking lubricants. Microemulsions employed as lubricants are commonly called semisynthetic fluids.

Several parameters differentiate microemulsions from emulsions. Most importantly, microemulsions are thermodynamically stable; that is, the state of lowest free energy is dispersed rather than separated. Therefore, the stability problems associated with emulsions are nonexistent. Microemulsions remain stable indefinitely, as long as they are maintained in appropriate ranges of pH, oil-to-water ratio, and temperature. These ranges may be very narrow to very broad, depending on the nature of the microemulsion. The diameters of the dispersed oil globules in microemulsions range from approximately 0.01 to 0.2  $\mu\text{m}$  (0.4 to 8  $\mu\text{in.}$ ), depending on the nature of the oil and the types and concentrations of emulsifiers. This small oil globule size is the feature that makes them appear clear to translucent. Additionally, the oil globule diameters are much more uniform in microemulsions than they are in emulsions.

Microemulsions are generally produced in the metalworking environment by adding a concentrate to water with agitation. The concentrate

generally contains oil, the emulsifier package, film-strength additives, corrosion inhibitors, biocides, and in some cases, EP additives. Dilutions range from about a 10 to 1 ratio of water to concentrate to as high as 60 to 1. Lower dilutions are used in operations where lubrication is more important, whereas higher dilutions are used where cooling is more important. Concentration is commonly determined with a handheld refractometer and a calibration chart that relates the instrument reading to concentration.

Microemulsions offer good resistance to corrosion and to microbial attack, as well as excellent stability and cooling. They suffer from higher initial cost, difficulty of disposal, and a stronger tendency to foam. Microemulsions formulated with fatty acid soap-type emulsifiers tend to degrade rapidly in hard water because of the formation of insoluble calcium and magnesium carboxylates.

**Micellar Solutions.** When emulsifier molecules are dissolved in water, they tend to aggregate into larger units called micelles. Micelles are formed spontaneously because of the fact that the lipophilic portion of the emulsifier molecule tends to aggregate in the interior of the micelle, whereas the hydrophilic portion tends to penetrate into the water phase. Figure 7 illustrates, in two dimensions, the relation between a molecule of a typical anionic emulsifier, sodium dodecyl sulfate, and the spherical micelle that it forms in water. Micellar solutions used as metalworking lubricants contain neither petroleum oils nor synthetic hydrocarbons. They contain film-strength additives, EP additives as appropriate,

and corrosion inhibitors solubilized within the interior of the micelles. Because micelles have diameters typically between approximately 0.005 and 0.015  $\mu\text{m}$  (0.2 and 0.6  $\mu\text{in.}$ ), micellar solutions are transparent to the eye and, like microemulsions, are thermodynamically stable. Because virtually all of the components of micellar solutions are obtained by chemical synthesis, they are often referred to as either synthetic lubricants or chemical coolants.

Like emulsions and microemulsions, micellar solutions for metalworking are generally formed by the addition of a concentrate to water with agitation. Dilutions typically range from a water-to-concentrate ratio of 10:1 to about 50:1, depending on the application. As in the case of microemulsions, concentration is determined by refractive index.

Micellar solutions that contain no alkali metal soaps or amine fatty acid soaps show good stability in hard water. They are more resistant to microbial attack than either emulsions or microemulsions. They can be formulated to reject tramp oils, which can then be skimmed and collected for disposal or recycling. They have excellent cooling capability, provide excellent corrosion control, and have a long, useful life.

On the downside, because micellar solutions tend to cost more initially, a total cost-benefit analysis should be performed. Additionally, because they are highly fortified with emulsifiers, foam can be a real problem. Antifoaming agents can be added to control foam. Micellar solutions, in general, have lower lubricating capability than other types of metalworking lubricants. This limits their applications to those

**Fig. 6** Sodium oleate. (a) Chemical formula. (b) "Straight pin" depiction. (c) Oil-in-water emulsion stabilized by sodium oleate emulsifier

**Fig. 7** Sodium dodecyl sulfate. (a) Chemical formula. (b) Sodium dodecyl sulfate micelle in water

metal-removal operations with low tool pressures and high tool speeds where cooling is of paramount importance. In such operations, tool life can be extended as much as 250 times by using micellar solutions, compared with straight oils. One final drawback is waste disposal. It is often very difficult to separate the organic materials from water because of their nature. The organic materials tend to remain soluble over wide ranges of pH, temperature, and salt concentration. It is often necessary to resort to sophisticated techniques, such as reverse osmosis, for disposal.

**True solutions** differ from micellar solutions in that the molecules of active substances do not form micelles when dissolved in water. Rather, each ion is solvated by water molecules. Because essentially all film-strength additives and EP additives either form micelles or require micelles to dissolve them, true solutions offer lubricating qualities that are little better than those of water.

True solutions are used in cases where cooling is the only consideration. In these cases, their advantages are low cost, very high cooling, stability, low foam, and a very long life. Typical true solutions often contain nothing more than a corrosion inhibitor, such as sodium nitrite, in water.

**Solid-Lubricant Suspensions.** As previously noted, lubricants for specialized uses often contain solids in the form of finely divided powders suspended in a liquid carrier, such as oil or water. The liquid carriers may also contain soluble additives of the classes previously mentioned. One of the most common suspended substances is colloidal graphite, with specific surface areas that often exceed  $100 \text{ m}^2/\text{g}$  ( $3 \times 10^4 \text{ ft}^2/\text{oz}$ ). It is used extensively in hot forging and extrusion of both ferrous and nonferrous metals. Molybdenum disulfide is another commonly used suspended solid. Both graphite and molybdenum disulfide are compounds that possess layered crystal structures with weak forces bonding the layers together so that they are easily sheared. They function by plating onto tools and workpieces such that the weak shear direction is parallel to the surfaces. As the tool and workpiece surfaces are brought together, they form a solid film, preventing tool-workpiece contact and shear along the weak shear plane, thereby reducing friction.

Other types of solids that are suspended as fine powders in some metalworking lubricants include mica, polymers such as Teflon, certain metal oxides, and glasses. Mica has a layered structure and functions in a way similar to graphite. Polymers mechanically separate metal surfaces, lower friction, and reduce metal transfer. Hard metal oxides, such as aluminum oxide, have good wear resistance but high friction coefficients. Soft oxides, such as lead II oxide, give relatively low friction coefficients that decrease at higher temperatures, where the mechanism of deformation changes from fracture to plastic flow. Glasses are suspended in lubricants for use in metalworking operations at high temperatures, where they soften on hot die

and workpiece surfaces and function as parting agents of low shear strength.

Solids can be kept in suspension by using surface active agents, mechanical agitation, or both. Problems can arise if not enough care is taken and the solid is allowed to "settle out." Also, metalworking lubricants containing suspended solids tend to produce buildup on tools and workpieces that are difficult to clean. These problems can be minimized by the appropriate formulation.

## Lubricant Effectiveness

Selection of an appropriate lubricant for a specific sheet-metal forming operation or for a series of different operations is often a costly hit-or-miss proposition. There are, however, laboratory test procedures that can often reduce the possibility of error.

Because of the difficulty of translating laboratory test results to an operating condition, several simulation tests have been developed to screen lubricants for sheet-metal forming. Small-capacity presses have been installed as test machines with the ability to control speed of forming, metallurgy of tools and work metal, and lubricant application method.

Strip drawing through a wedge-shaped die on a tensile machine has been developed to measure lubricant effectiveness. One end of the strip is gripped and pulled through the die. The die may also be modified in order to simulate drawing over draw beads. In these tests, resistance to sliding is measured for different lubricants applied to the strip.

Standard deep-drawing tests, such as the Swift cup test, can also be used to measure lubricant effectiveness. Poor surface finish, score marks, or splits are indications of unsatisfactory lubrication. More information on tests for measuring the drawability of metals is available in the article "Formability Testing of Sheet Metals" in this Volume; Ref 7 and 8 include more details on evaluation of lubricant effectiveness. The larger the blanks formed and the deeper the cup, the more effective the lubricant film will be. A wide variety of punch and sheet metal geometry, size, and tool material can be used along with the lubricant coating. The limiting draw ratio (LDR) depends on the draw ratio (DR), which is equal to the ratio of the blank diameter to the punch diameter. For a given punch diameter, the greater the blank diameter, the more severe is the operation. The LDR is the maximum DR that results in a satisfactory cup.

**Lubricant Breakdown and Galling (Ref 1).** Even under processing conditions that appear mild in comparison with bulk deformation processes, lubricant breakdown is often encountered because the lubricant is wiped off in the course of sliding and asperities are exposed to direct contact with the die. Tool pickup then follows, which in turn leads to scoring or galling of the workpiece surface. Because galling is an event that follows local lubricant failure, it is

greatly affected by workpiece and die topography and by adhesion between the contacting materials.

Galling is typical of all processes in which the workpiece slides over the die. Galling is a result of localized adhesion and is, therefore, affected by a number of process variables:

- An asperity of low slope deforms and is pushed into the bulk. As the asperity slope increases, a point is reached where a bulge forms, which is then removed by a shearing (cutting) action.
- Debris formed in the course of sliding may be trapped and rendered harmless in valleys of the sheet surface, may become embedded in other sheet asperities, or may lodge against die scratches. Repeated encounters at many points result in deformation, thinning, and lamination of particles; some of them may even roll up. If adhesion to the die is high, new large asperities form, which lead to scratching, formation of more thick particles, and galling.
- Galling is affected by the macroscopic tool geometry. It usually originates at transition points such as die radii, but its severity greatly increases if the already damaged sheet, with embedded particles, is dragged along a parallel surface such as a die land.
- The incidence of galling is a function also of the stiffness of the system. Damage is localized in a soft (constant-force) system, whereas it is widespread and uniformly distributed in a stiff (constant-gap) setup.

Both workpiece and die roughness have significant influences on the incidence and severity of galling:

- A smoother sheet surface presents a larger bearing area and is more prone to galling. For a given reduction in thickness, smoother sheet galls after shorter sliding or fewer repeat tests. This effect can be quite dramatic; a small change in roughness is sufficient to initiate galling in drawing of materials prone to pickup.
- The size and distribution of asperities is most important. For a given average roughness, larger flat plateaus give longer contact (sliding) distance and more galling. For a given bearing area, a smoother sheet has smaller plateaus but a much greater peak density, and thus it presents more points for sliding contact and is more prone to galling.
- The directionality of the sheet surface profile has a marked effect. Plateaus aligned in the direction of sliding present longer sliding distances and are more likely to allow embedment of the debris. Thus, they are more harmful than transverse ridges, which trap debris in valleys and may even act as rasps to remove incipient pickup from the tooling.
- The depth profile of the sheet surface is important because it determines the ability of the surface to entrap lubricants and accommodate wear debris.

- There has been some success in defining what sheet surface is best, even though there is no general agreement. Invariably, steel sheets with bearing areas of less than 20% at 1.5  $\mu\text{m}$  from the surface prove to be nongalling, whereas those with larger bearing areas (and those whose bearing areas increase more rapidly with depth) are prone to galling.
- A rough die surface is desirable only on the punch because it then increases the LDR and the depth of draw in automotive pressworking. If the sheet material has to slide over die elements, roughness leads to higher friction, lubricant breakdown, and galling, although the effect depends also on die composition and hardness. The harder the tool, the more damaging is its roughness. Thus, a cast iron die or a nonhardened steel die can be rougher than a heat treated steel or WC die.

Because of their importance in adhesion, materials composition and hardness have decisive influences. Adhesion between die and workpiece governs whether die pickup will occur and, if it occurs, whether it will be cumulative. Major factors are:

- Compatibility of die and workpiece materials can be quite subtle. For example, increasing the magnesium content of aluminum alloy 2036-T6 reduces adhesion. In steels, segregation of manganese, chromium, and other alloying elements has been suspected to reduce adhesion, perhaps by strengthening the surface layer. Steels precipitation hardened with niobium or titanium additions are more resistant to galling than solid-solution (Si, Mn) hardened steels for the same reason. These effects should be quite general. Martensitic transformation induced in austenitic stainless steel increases friction and draw forces but reduces adhesion.
- Surface composition plays an important role. A sheet subjected to sliding contact galls more readily on subsequent contact. An untouched surface has surface layers that may or may not protect it. For example, steel pickled in HCl

may be more prone to galling than that pickled in  $\text{H}_2\text{SO}_4$ .

- The hardness of the workpiece material plays a role. High-strength steels are not much more adhesive than low-carbon steels but generate higher pressures and are more prone to galling, especially on draw beads. Previously strain-hardened material undergoes less hardening during working, and this is beneficial because it reduces the thickness of wear debris. However, the sheet hardness should be not more than half the tool hardness, otherwise, strain hardening of the asperities makes them strong enough to cause abrasive wear of the die.

### Lubricant Application (Ref 9)

The method used to apply the forming lubricant directly influences handling, part quality, and direct costs, as well as indirect costs (cleaning) and the metal-forming operation itself. It is very important to deliver the appropriate volume of lubricant to the right location with the correct velocity at the right temperature in order to achieve optimum lubrication. Some of the more widely used application methods are discussed in this section.

**Roller coating** (Fig. 8a) is frequently used to coat strip before the strip enters the press. The strip passes through rollers, either top and bottom rollers or one or the other, and is coated with lubricant. The lubricant is fed to the roller either by dripping or by having the roller revolve, in a lubricant reservoir. The roller may be the same width as the strip and may be made of various materials. Pressure on the rollers can be varied to control lubricant thickness.

**Air or airless spray devices** (Fig. 8b) are used to apply lubricant to preselected areas of the workpiece and/or tooling at the required frequency. Generally, higher-viscosity lubricants are applied by airless spray rather than by air spray units.

**Drip application** to the workpiece (Fig. 8c) can be used effectively when parts are relatively

small and the cost of alternative application devices is not justified by the production demand. Heavy lubricants cannot be applied readily by this method, nor can the geometry of application be tailored selectively.

**Flood application** methods (Fig. 8d) require suitable press modifications to provide for recirculation of the fluid. Waterproofing to protect sensing elements must be provided for if a water-base fluid is used, and lubricant flooding must be controlled to confine it to the press work area. Flooding can be very useful when cooling is desirable and debris must be removed continually from the work area.

### Control of Lubricant Characteristics

Maintaining the physical and chemical properties of lubricants is central to control of the sheet-metal forming process itself. Table 3 lists some important characteristics of metal-forming lubricants for which tests have been developed and the applicability of testing to various types of lubricants. Control methods developed under the aegis of the American Society for Testing and Materials (ASTM) are widely used. Some of the ASTM test methods for important characteristics are discussed next.

**Viscosity** (ASTM D 445, D 446, and D 88) is as important as any physical property of fluids used in sheet-metal forming. Viscosity control is based on the measurement of the time required for a lubricant to flow through a fixed orifice at a controlled temperature.

**Sulfur and chlorine** (ASTM D 129 and D 808) are measured by carrying out a controlled combustion of a lubricant sample in a so-called bomb. ASTM D 129 describes a technique used for sulfur, and ASTM D 808 describes the appropriate technique for chlorine.

**Corrosion potential** can be very important in both evaluating the appropriateness of a specific lubricant and for purposes of corrosion control during continued use. The methods most commonly used, for example, ASTM D 130 for copper-base metals and ASTM D 1748 for steel

Fig. 8 Four common methods of applying lubricants. (a) Roller coating. (b) Spraying (simple spray apparatus shown). (c) Drip application. (d) Recirculating flood

corrosion test strips, are based on the potential of water-lubricant interaction with the metal surface in a controlled way. Immersion in the fluid at elevated temperatures or exposure of a lubricant-coated strip in a humidity cabinet are techniques frequently used; they may be varied in many ways to attempt to duplicate as closely as possible particular operating conditions.

**Emulsion stability** is often of importance in maintaining a reproducible and reliable parts production line. A common method used to evaluate stability is ASTM D 1479, in which water available at the work site is used to make an emulsion. The emulsion is then stored for a specified period of time and evaluated. The concentration of oil in the bottom portion of the sample is a measure of the emulsion stability.

**Fatty compounds** are frequent components of a metal-forming lubricant. The test method ASTM D 94, using saponification number as a basis for fat determination, may be used as long as the basic fat component is known.

**Hydrogen ion concentration (pH)** is important in water-base lubricants. Variation of pH can be an important indication of fluid contamination or degradation due to biological or chemical reaction. Monitoring of pH on a regular basis can serve as an important control of fluid properties in a manufacturing environment. The pH can be measured with specially prepared pH paper or a pH meter.

## In-Plant Control

Very important test procedures that do not require sophisticated laboratory facilities or

highly skilled personnel are used for in-plant control. Some of the test procedures useful for lubricant control in plants are discussed next.

**Emulsion concentration** is one of the most important characteristics of a lubricant in metalworking. Variation in concentration occurs during use because of water evaporation; selective dragout; and, frequently, lack of emulsion makeup control. A number of control techniques can be used successfully in the plant. These include the use of titration, a refractometer, and acid split.

*Titration* can be used to measure either emulsifier concentration or, in turn, emulsion concentration. Anionic emulsifiers can be titrated by using a cationic material with an appropriate indicator. Water hardness effects on the titration must be accounted for to improve the reliability of the titration.

A *refractometer* may be used to measure concentration. The refractive index of the emulsion or water-base solution varies with concentration. Fluid compositions also vary; therefore, the refractive index must be calibrated for each fluid. Fluid contamination can cause a false index reading and may prevent use of this measurement method.

*Acid split* is used to determine water concentration in an emulsion. The emulsion is split by using a strong salt solution or acid. If oil (tramp or machine oil) enters the emulsion, then the acid split will reflect all the oil present, and thus incorrect concentration values will be obtained.

**Corrosion tests** have been developed for measuring the possibility of change in this characteristic of a lubricant. A plant procedure is

based on taking pieces of sheet metal to be formed, coating them with the lubricant to be used, and placing the specimen in a plant location most likely to encourage corrosion. Experience with a procedure standardized as much as possible with respect to lubricant, metal, and environment can be useful for plant testing. Various tests using metal coupons coated with lubricant and subjected to a high-humidity environment (humidity cabinet) can also be used. Cast iron blocks and chips can be used for accelerated testing, using any of a number of procedures involving contact with lubricant and subsequent aging in a selected room or plant environment.

**Biological testing** in the plant can be carried out to advantage if reasonable control of test conditions can be maintained. Dipsticks have been developed that consist of a plastic substrate coated with a nutritive gel selected for growth of either bacteria or mold, as desired. The method, though qualitative, is useful as a fluid control procedure in the plant. References 10 and 11 contain more information on control of lubricant characteristics.

## Lubricant Toxicity (Ref 12)

Because the environment, as well as the biochemical characteristics of the human body, are extremely complex, effects on health in the workplace are difficult to isolate and measure. In general, exposure to sheet-metal working lubricants may result in dermatitis, acne, tumors, and pigment changes in the skin. All of these may occur also from exposure to other by-products in the workplace, in the home, or in the environment in general.

Skin patch tests of a suspect material may reveal the potential for dermatitis. A small patch is coated with the material in question and taped to the skin.

The Ames test, which measures the effect of a test material on bacteria, has been used as a screen for possible causes of mutagenic effects in humans. Most materials that may cause mutagenic effects are not necessarily carcinogenic. Evaluation of a metalworking fluid for its possible adverse biochemical effects should be a part of the lubricant selection process. The requirement of a completed material safety data sheet on all chemicals and their mixtures can serve as an important source of information for the screening procedure. Appropriate work practices and personal hygiene can significantly reduce adverse biochemical effects.

## Microbiology of Lubricants

Microbiological contamination of lubricants can be a serious problem. When water is part of the composition of a metalworking fluid, microbes can grow in the fluid, either deliberately or accidentally as a result of contamination. Bacteria are the main problem in mineral-oil

**Table 3 Lubricant characteristics and their applicability to various types of lubricants**

Characteristic	Lubricant system

emulsions; in water solutions, molds and yeasts are the principal microbiological contaminants. These microbes feed and grow on one or more of the lubricant constituents or contaminants. If they grow by attacking a single constituent, the constituent can be so altered chemically in short order, frequently as rapidly as in one day, that the lubricant no longer operates effectively as intended. An emulsifier may no longer promote stable emulsification, a rust-preventive additive may no longer prevent rust formation, or a lubricity additive may no longer provide an effective lubricant film.

Anaerobic bacteria, often present in fluids, operate in the absence of oxygen and cause the breakdown of sulfur compounds in the fluid, creating the strong rotten-egg odor that may occur in the fluid reservoir. Aerobic bacteria grow in the presence of oxygen and are the most aggressive in promoting overall chemical breakdown of the lubricant. Molds and yeasts, when present, do not drastically degrade lubricant chemistry; they do, however, block filters, and may build up on tools and generally have a disagreeable feel and appearance.

Bacteria and mold or yeast infestation of the lubricant may be controlled by appropriate formulation of the lubricant, use of an effective biocide, pasteurization, and sometimes effective filtration. Good practices involving clean work habits and avoidance of contamination of the fluids by plant dirt, food, and so forth will contribute to longer life of fluids. References 13 to 15 contain more detailed information on the effects of microbiological contamination.

## Environmental and Occupational Health Concerns

Concerns about the environment, health, and safety have led to the enactment and enforcement of a number of laws and regulations. Some of the most important of these as they affect the use and disposal of sheet-metal forming lubricants are discussed here.

**The Environmental Protection Agency (EPA)** was established by the U.S. Congress to ensure protection of the environment in which we live and work. Over the years, clean air and water have become a subject of increasing concern. Several acts addressing these concerns have been passed, requiring enforcement by EPA. Some of the more important acts are:

- The Toxic Substance Control Act, designed to regulate the manufacture, processing, distribution, use, and disposal of chemicals. Material Safety Data Sheets are required for all lubricants, with information about the toxicity, handling, and safe disposal of such materials.
- The Clean Air Act, as amended in 1977, which specifically regulates the concentration of volatile lubricant components in air. It established permissible concentrations that must not be exceeded in the workplace.

- The Water Pollution Control Act regulates the passage of waste into the water supply. The condition, type, and concentration of waste that may be permitted to enter the water supply is established and regulated. Disposal of lubricants, if it involves entry into a water system, must satisfy the appropriate criteria for disposal.
- The Resource Conservation and Recovery Act (RCRA) regulates hazardous waste management and disposal. Lubricants, if they contain hazardous components, are categorized as hazardous materials and must be stored, transported, and disposed of as prescribed by regulation. Appropriate records must accompany each step, as regulated.

**The Occupational Safety and Health Administration (OSHA)** is concerned with safe working conditions in the workplace. The impact of occupational safety and health legislation on lubrication as practiced in the workplace concerns prevention of occupational illnesses due to hazardous or toxic chemicals. Companies are required to record all injuries or illnesses as they occur. Relative toxicities of chemicals in the workplace have been surveyed by OSHA.

**Product liability** is of increasing concern because of the exploding cost of defending a product liability case as well as the bringing of nonmeritorious claims to court. At the same time, increasing attention has been paid to safer, better products as well as a safer, better work and living environment. Lubricant manufacturers and users are faced with claims for improper formulation, usage, and performance. Appropriate steps to anticipate and eliminate possible product liability claims occupy increasing time and attention on the part of both the supplier and user of lubricants.

The laws and regulations described in this article illustrate only a few of the more important ones that govern and regulate the use, disposal, and manufacture of sheet-metal forming lubricants. New developments in lubrication technology will surely be conditioned by this regulatory and liability environment.

## Lubricant Selection

Selection of an appropriate lubricant for a specific sheet-metal forming operation depends on a number of diverse criteria that must be successfully satisfied:

- Effect of lubricant on the forming operation (effect on both tool wear and part tolerance and finish)
- Application method and efficiency thereof
- Maintenance of lubricant performance, taking into account problems of recirculation, testing, and disposal
- Corrosion of tooling, machine, and finished parts
- Cleaning
- Welding, painting, or coating of the work material

- Worker response
- Supplier support
- Toxicity and health
- Cost, including cost of lubricant and its effect on overall product cost

A wide variety of operations are commonly used to form parts from sheet metal. Blanking, piercing, ironing and stretching, forming, drawing, fine blanking, and spinning are some of the operations that are used separately or in sequence to form parts, and are discussed in other articles in this Volume. Unlike bulk deformation processes, the temperature increase in sheet-metal forming is generally low unless the complexity of deformation and/or the strength of the material is very high. Generally, except in the case of ironing, sheet-metal forming involves little or no thickness change. Deformation is generally biaxial in the plane of the sheet. However, there can be considerable relative motion between tool and workpiece. Further, the area of tool contact is often large. Surface finish and part tolerance depend on tool geometry and finish, speed and temperature of deformation, the combination of forming steps required, and the choice and application of lubricant. Tables 4 and 5 list some of the types of lubricants used successfully in sheet forming of various metals at room temperature and at elevated temperatures. The type of metal, complexity of part shape, part tolerance, and surface finish specifications all influence the choice of lubricant. The more critical the operation, the more important the need for film strength and adhesion of the lubricant film to the metal substrate. Further, there may be a need for increased film thickness.

The relationship of many process variables, including speed of operation; tool geometry; number and severity of discrete forming operations; worker exposure to lubricant; fluid makeup; circulation, recycling, and disposal; and the effect of the lubricant film on subsequent operations such as welding, cleaning, and plating, influence the choice of lubricant. A simple recommendation based on material, tooling, and process may prove to be far from optimal; many other factors can and should influence lubricant choice.

Nevertheless, in order to give some background information that may provide guidelines in the selection of a lubricant, a number of processes applied to various sheet materials relative to the choice of an appropriate lubricant are discussed subsequently. A summary of commonly used lubricants in sheet forming is in Table 2.

## Lubrication of Carbon and Low-Alloy Steels

A wide range of lubricants are successfully used to form steel sheet. The speed of operation and resulting temperature, as well as thickness of stock and complexity of shape, influence lubricant choice. Oil-, solvent-, and water-base fluids,

**Table 4 Lubricants for forming of specific sheet materials**

Metal or alloy	Recommended lubricants for:	
	Cold forming	Hot forming
Aluminum alloys	Synthetic solutions, emulsions, lanolin suspensions, water suspensions, soap solutions, mineral oil plus fatty oils	Graphite suspension
Copper alloys	Emulsions plus fatty oils, mineral oils plus fatty oils, soap suspensions, water suspensions, tallow suspensions, synthetic solutions	Pigmented pastes, graphite suspensions
Magnesium alloys	Solvent plus fatty compounds, mineral oils plus fatty compounds	Graphite plus molybdenum disulfide, soap plus water, tallow plus graphite
Nickel, nickel-base alloys	Emulsions, mineral oils plus EP additives, water plus chlorine additives, conversion coatings plus soap	Graphite suspension, molybdenum disulfide suspension, resin coating plus salts
Refractory metals and alloys	Copper plating	Molybdenum disulfide, graphite suspension
Carbon and low-alloy steels	Emulsions, soap pastes, water, fatty oils plus mineral oils, polymers, conversion coating plus soap, molybdenum disulfide or graphite in grease, synthetic solutions	Graphite suspension
Stainless steels	Fatty oils plus mineral oil, water, polymers, conversion coating plus soap, mineral oil plus EP additives, pigmented soaps	Graphite suspension
Titanium, titanium alloys	Water, pigmented soaps, polymers, conversion coating plus soap	Graphite and molybdenum disulfide suspension
EP, extreme-pressure		

**Table 5 Commonly Used Sheet Metalworking Lubricants and Typical  $\mu$ m Values**

Lubricants are listed according to increasing severity of conditions.

Material	Shearing, bending(a)	Pressworking(a)	$\mu$ m(b)
Steels	Dry (pickle oil)	Dry (pickle oil)	0.2
	EM (MO + EP)	Soap solution	0.15
	MO + EP	EM (MO + fat) (+EP)	MF
		MO + fat (+EP)	MF
		Fat (tallow)	0.07
		Soap (water-soluble) film	0.05
		Wax (chlorinated)	0.05
		MoS <sub>2</sub> or GR in grease	0.05
		Polymer coating (+MoS <sub>2</sub> )	0.05
		Phosphate + soap	0.05
		Metal (Sn) + EM	0.05
		EM (MO + Cl) (or fat)	0.2
		MO + Cl additive	MF
Stainless steels and Ni alloys	EM (MO + Cl)	Chlorinated wax	0.07
	MO + Cl additive	Polymer coating	0.07
		Oxalate + soap	0.07
		Metal (Cu) + MO	0.05
	EM (MO + fatty derivatives)	EM (MO + fatty derivatives)	0.15
	MO + fatty derivatives	MO + fatty derivatives	MF
		Soap or wax (lanolin) coating	0.05
Al and Mg alloys		Polymer coating	0.05
		Warm: GR film	0.1
	Soap solution	Soap solution	0.1
	EM (MO + fat)	EM (MO + fat) (or fat)	0.1
	MO (+fat) (+EP)	Drawing paste (EM of fat)	0.1
		Fat (tallow)	0.07
		Pigmented tallow (MoS <sub>2</sub> , etc.)	0.05
Cu and Cu alloys		Wax coat	0.07
		Oxide + soap coating	0.07
		Polymer (+MoS <sub>2</sub> )	0.05
		Fluoride-phosphate + soap	0.05
		Metal (Cu or Zn) + MO (or soap)	0.1
		Warm: MoS <sub>2</sub> or graphite	0.2
		Cold: Al-Fe-bronze dies with wax	0.07
Ti alloys	MO + EP		
Refractory metals	MO + EP		

(a) EM, emulsion of ingredients shown in parentheses. MO, mineral oil; of higher viscosity for more severe duties, limited by staining. EP, extreme-pressure additive (S, Cl, and/or P; also sulfochlorinated fats). (b) MF, mixed-film lubrication:  $\mu$ m = 0.15 to 0.05. Source: Ref 1

as well as pastes and gels, may be effective, depending on operating conditions.

**Light Pressing.** Industrial experience shows that almost any lubricant (light oil, dilute soap solution, or emulsion) is satisfactory. The insensitivity of steels to lubrication may well be due to the presence of residual films. Annealed and pickled sheet is coated with a corrosion-prevention lubricant, and cold-rolled sheet carries an oily residue. After degreasing with orthosilicate solutions, a silica film remains, which is likely to have a parting action.

**Blanking and Piercing.** Straight oil, compound oil, or emulsions with sulfur, chlorine, and/or fatty esters are used for most operations. Solutions may be used when the operation is less severe.

**Coining.** Because die buildup must be prevented, light oils straight or compounded with fatty additives or chlorine-containing additives are used. Water-base solutions may be effective when formulated with alkanolamides, fatty esters, and/or long-chain derived fatty acid soaps.

**Other Operations.** Compression, tension, binding, or shearing forces may occur during forming on a particular part; therefore, an appropriate choice of lubricant viscosity and chemistry varies widely from part to part, depending on part configuration. Essentially all classes of lubricants have been successful. Generally, however, the present emphasis is on formulating solutions or emulsions that prevent galling or tearing of the sheet metal.

**Multislid Forming.** Light compounded oils and water-base emulsions and solutions with chlorine and fatty additives are used successfully. Care must be taken to prevent buildup on the dies and corrosion of machine or formed parts when water-base lubricants are used.

**Deep Drawing and Stretching.** Progressive- and multiple-die sets are used frequently in deep drawing, and thus carry-through of the lubricant becomes more and more important. Multiple-die lubrication sites that provide die lubrication at succeeding stations may be an alternative method for ensuring adequate lubrication. Compounded oils and emulsions or pastes are being used successfully. Chlorinated compounds and fatty esters are commonly chosen additives. Soap-base lubricants are also applied frequently and successfully in deep drawing.

Severity of duty in deep drawing and stretch drawing is determined by the degree of drawing and sliding, and by sheet thickness.

For light duties, viscous oils, fatty-oil emulsions, or water-soluble polymer formulations are sufficient. When pickup is a problem, a sulfur additive is needed.

For more severe duties, highly viscous oils with fatty oils and EP additives, or drawing pastes based on pigmented soap-fat formulations, can be used. Pigments such as talcum, chalk, and ZnO are good parting agents, but their removal presents difficulties. Fats, particularly tallow, are successful.

Soaps, such as zinc stearate and the specially formulated dry soaps, are excellent, as are waxes. However, on deposition from aqueous solutions, the heating required to drive off the water causes

aging in rimming steels. Chlorinated wax is one of the heaviest-duty lubricants.

Graphite and  $\text{MoS}_2$  do not necessarily ensure low friction, but when added to a fat such as tallow, or to a drawing paste, they give good results. They are effective under severe conditions such as drawing of high-speed steel. Removal is again a problem, and this can be minimized by applying the layer-lattice compound locally to the die radii.

Polymers such as PE and PTFE have often been found to be useful and, as discussed in conjunction with mill-applied coatings, have found their specific fields of application.

**Heavy Drawing and Ironing.** High surface pressures and large surface expansions demand a phosphate/soap system. Reactive oils do not give quite the same performance but are suitable for moderately heavy duties. Among the layer-lattice lubricants, bonded  $\text{MoS}_2$  coatings can survive. An alternative is to coat with tin 0.25 to 0.75  $\mu\text{m}$  (10 to 30  $\mu\text{in.}$ ) thick, as in production of drawn and ironed cans, and to lubricate and cool with the aid of a compounded emulsion.

**Spinning.** Both lubrication and cooling are important effects provided by appropriate lubricant choices. Water-base emulsions and solutions containing chlorinated or sulfochlorinated additives and/or fatty esters are used. Nonpigmented water-base pastes are also effective.

**Roll Forming.** Water-base emulsions and solutions have been used to form both bare and coated steel. In the case of galvanized steel, white rust can be a problem if water-base lubricants are used and not properly applied and removed. Solvent-base fluids are often the preferred lubricant, particularly when minimal residue is important. Light oils may also be used, both compounded and uncompounded with chlorinated compounds, soaps, or fatty esters.

### **Lubrication of Stainless Steels**

In general, stainless steels are more difficult to form than carbon or low-alloy steels because of their higher strength. Care must be taken in the choice of chemically reactive lubricants containing sulfur or chlorine. Furnace treatments should be carried out on formed parts after removal of the lubricant film. Sometimes this step may be avoided if high molecular weight polymers or complex fats are used in lubricant formulation. The lack of reactivity coupled with the frequent demand for very high surface quality can present challenges.

With steel dies, a viscous oil with chlorine additives suffices for light duties. Performance improves with increasing viscosity and also when polybutenes are used. Neat chlorinated paraffins give the best performance. Graphited tallow and pigmented oils and pastes are sometimes used, but the graphite causes carburization on annealing and presents difficulties of removal.

Of the separating films, dry soaps and waxes such as beeswax are adequate for medium duties. Chlorinated polymers deposited from aqueous or organic vehicles are more satisfactory, as are polymers in general. Peelable films are indispensable in making parts with high surface quality. However, for the most severe duties, including ironing, an oxalate/soap coating is best. If necessary,  $\text{MoS}_2$  may be applied on top of it. When the die is coated with TiC, chlorinated oil suffices. Alternatively, the workpiece can be coated with a metal such as lead, but since the advent of the oxalate coating, this is seldom practiced.

Martensite transformation induced by deformation can lead to cracking of deep drawn, metastable austenitic stainless steel cups. Lubrication seems to play no role in this.

**Blanking and Piercing.** Solutions and emulsions containing sulfur and/or chlorine are particularly effective for lighter-gage material. Oils compounded with sulfur and/or chlorine are effective in heavier-gage material.

**Multiple-Slide Forming.** Oil- and water-base fluids are used successfully. Solutions with complex esters and fatty compounds have been used, successfully eliminating cleaning of parts before use.

**Deep Drawing.** Because of the high work-hardening characteristics of some stainless steels and attendant high die pressure and temperatures, oils with EP additives such as sulfur, chlorine, and phosphorus are most often the lubricants selected. Pigmented and nonpigmented pastes are often used with or without EP additives.

**Roll Forming.** Thin-gage sheet may be formed by application of solvent-base as well as water-base fluids at the roller. Thicker material and/or more complex shapes, on the other hand, require oils or emulsions compounded with fatty oils, EP additives, and soaps.

### **Lubrication of Heat-Resistant Alloys**

In general, heat-resistant alloys (complex iron-, nickel-, and cobalt-base materials) as a class use lubricants that are suitable for stainless steel. Cobalt-base alloys are particularly difficult to form into sheet because of their high strength and relative inertness. Care must be taken to avoid embrittlement by sulfur diffusion in nickel-base alloys. Pigmented lubricants are difficult to remove after forming, and this may discourage their use. More information on forming of heat-resistant alloy sheet is available in the article "Forming of Nickel and Cobalt Sheet Alloys" in this Volume.

**Blanking and Piercing.** Soap-base oils and emulsions are used with and without chlorinated additives. Wax and polymer additives may be used if the blanking step is complex.

**Spinning.** Chlorinated additives in an oil base as well as in emulsions containing fatty esters are effective. Soap-base pastes are also often chosen for application.

### **Lubrication of Refractory Metals and Alloys**

Although warm or hot forming of materials such as molybdenum, tungsten, tantalum, niobium, and their alloys is often required, room-temperature deformation is successfully carried out using metal coatings with auxiliary lubricant application.

The main problem in lubrication of refractory metals usually is brittleness or adhesion. The ductile-to-brittle transition temperature of tungsten sheet is between 100 and 400 °C (212 and 750 °F). Forming is done at elevated temperatures. Molybdenum and its alloys (TZM) are also too brittle to be formed at room temperature. At around 400 °C (750 °F),  $\text{MoS}_2$  is the preferred lubricant, although graphite has also been used. Dies of aluminum bronze have been used with castor oil as the lubricant. Bronze dies with beeswax, or chromium-plated steel dies with graphite, are satisfactory in forming of uranium. The basic problem with tantalum is its severe galling on steel dies. One solution relies on bronze dies with beeswax.

**Drawing.** Fluorinated complex polymers are used to form tantalum; graphite in fat has been used for forming niobium. Both metals may be formed at room temperature.

**Spinning.** Room-temperature spinning of niobium has been carried out using molybdenum disulfide in oil or graphite in a soap-base paste.

### **Lubrication of Aluminum and Aluminum Alloys**

Aluminum and aluminum alloy sheet may be stained or corrosion may occur through the improper choice of lubricant. Aluminum oxides build up during forming and may necessitate cleaning of both parts and equipment. The lubricant may contribute to undesirable buildup. Lubricant chemistry differs from the chemistry used in formulating lubricants for steel and refractory metals or high-temperature alloys.

For light pressworking, low-viscosity mineral oils, synthetic oils, or oil-base emulsions are suitable, invariably with boundary additives.

For more severe drawing and stretch drawing, the oil viscosity is higher, the emulsion is less diluted, and the boundary additive concentration is higher. Oils with EP additives are also used but are difficult to justify unless it is expected that the tool can develop protective films. When pickup is concentrated at specific areas of the die (such as draw beads), a concentrated lubricant may be applied locally.

Solid-film lubricants such as soaps and waxes are useful—especially if they possess boundary lubricating qualities. Graphite is less favorable because its success depends very much on application and because it leads to corrosion problems. Better is  $\text{MoS}_2$ , which yielded higher friction but also larger draw ratios in rectangular deep drawing. Except for working at elevated temperatures, there should be no need for

layer-lattice lubricants. Polymers are used extensively in the form of precoated (painted) sheet. Peelable films of PVC or PE protect parts with critical surface requirements while providing excellent lubrication when oil is superimposed. Loose PTFE films are useful but are limited by their lack of ductility.

**Blanking and Piercing.** Oils or compounded oils of light viscosity are used. Fatty esters and chlorinated compounds are the compounding additions frequently chosen. Fatty compounded emulsions as well as soap-base solutions are also effective. Oxide deposits may be a problem with some compounded oils and emulsions.

**Roll Forming.** Solvent-base lubricants containing fatty esters as well as emulsions and solutions are frequently used lubricants. Light viscosity oils also may be used; however, oxide buildup on the rolls can be a problem. Soap-base lubricants are used if care is taken to prevent soap deposits.

**Deep Drawing.** Viscosity and lubricity are critical attributes of lubricants. Water-base fluids may be used if appropriate fatty additives and/or soap additives are used to provide the required barrier and lubricity. Oils of varying viscosity or dry soap films may be used for more difficult draws. Pastes that are soap- and fat-base have been applied successfully. Progressive draws involving multiple steps frequently should provide lubrication at more than one station.

**Spinning.** Waxes and soaps are effective lubricants. Colloidal graphite suspended in an oil carrier is also used successfully. Cleaning can be difficult depending on the severity of the spinning operation.

### ***Lubrication of Copper-Base Alloys***

Lubrication difficulties increase from copper (which does not form cumulative pickup) to brass to bronze. For light pressworking, medium-viscosity mineral oils, oil emulsions, or soap solutions are used. For heavier duties, fats are added—sometimes in concentrations up to 50%.

For deep drawing and stretch drawing, straight fatty oils or compounded mineral oils, emulsions, or soap-fat compounds are needed. The limiting draw ratio (LDR) increases with increasing viscosity. Depending on the severity of draw, oil or water-base lubricants in fluid or paste may be effective. Chlorine or sulfur EP additives are often encountered, although sulfur staining is a problem. Staining and/or corrosion of these metals in forming is a particular concern. Lubricants chosen must be formulated to prevent both from taking place. Dry soaps are effective as are, of course, polymers, including methacrylate resins. Layer-lattice compounds have been found to be effective but should not be needed except in working at elevated temperatures. Fillers such as kaolin have been used but, again, should not be needed.

**Multislid Forming.** Soap- and fat-containing oil and/or water-base lubricants are effective. Solvent-base lubricants containing a fatty ester

or an inhibited chlorine-containing compound may be used.

**Roll Forming.** All classes of lubricants using fatty compounds and/or soap-base additives are used successfully in water, oil, or solvent fluids.

**Deep Drawing.** Depending on severity of draw, oil- or water-base lubricants in fluid or paste form may be effective. Soap and fatty compounds, as well as inhibited chlorine-containing compounds, are commonly used additives.

### ***Lubrication of Magnesium Alloys***

Magnesium alloys are most often formed warm or hot. Forming at these elevated temperatures is not normally required for other metals of industrial importance. Only moderate deformation of magnesium alloys is possible at low temperatures, and then soaps, waxes, or (in more difficult cases) graphited tallow will suffice.

**Stretching and Drawing.** At temperatures to approximately 120 °C (250 °F), soap-base lubricants, fatty esters, polymer additives in oil and water, and pastes formulated with chlorinated additives are successful lubricant systems. At temperatures in excess of 120 °C (250 °F), the choice of lubricant is restricted to synthetic fluids formulated with soap, fatty esters, and/or chlorinated compounds. Above 230 °C (450 °F), graphite and/or molybdenum disulfide in various carriers are preferred.

More severe stretching and deep drawing must be done at temperatures from 220 to 370 °C (430 to 700 °F). The lubricant is invariably colloidal graphite in a volatile (organic or water) base. It is applied to the blank prior to heating by spraying or roller coating. To facilitate removal, the blank should not be etched prior to coating so as to retain the oxide, which is then removed together with the graphite coating. Caustic etching is followed by chromic acid-sodium nitrate pickling.

**Spinning.** At elevated temperatures, the synthetic fluids compounded with graphite and/or molybdenum disulfide are applied. Water carriers for the solid lubricants may be preferred to reduce the occurrence of smoke and the possibility of fire.

### ***Lubrication of Nickel and Nickel-Base Alloys***

These metals are difficult to wet with lubricants; thus heavy-duty lubricants with exceptional film-priming characteristics are necessary for effective lubrication. On the other hand, lubricants containing sulfur, chlorine, or solid additives such as zinc oxide or lead carbonate, if not removed from the nickel surface, can cause embrittlement of the metal.

**Shearing, Blanking, and Piercing.** Oils incorporating sulfur- or chlorine-containing additives may be used. Water-base lubricants of similar composition may be applied if they are

removed as soon as possible after forming to prevent embrittlement. Fatty esters and polymers have grown in application as components of formulated lubricants.

**Deep Drawing.** Soap-base pastes as well as oils with fatty esters, amides, and/or sulfur and chlorine additives have been used. Emulsions fortified with amides and polymers also have been formulated and applied.

**Spinning.** Pigmented pastes and chlorinated wax in oils are successful lubricants. Plain waxes and soaps are frequently important components of these lubricants.

### ***Lubrication of Titanium Alloys***

Galling of titanium alloys is a particular problem because of the affinity of the metal for die materials. Notch sensitivity and embrittlement may also lead to splitting or cracking of formed parts. Cold and warm forming may be carried out with suitable films designed to prevent metal-to-metal contact. Frequently, overlays of steel sheet or plastic sheet are used with an auxiliary lubricant.

Because of their limited ductility, titanium alloys are usually warm formed, although limited forming and drawing at room temperature are possible.

In cold working, the high adhesion of titanium to die materials necessitates the use of a continuous separating film, such as a polymer or, for stretch forming, even a dry wax. Only for light duties, such as roll forming, will an EP oil suffice. For heavier work, various surface treatments combined with wax or dry soap lubricants can replace the polymers. Oxidizing, fluoride/phosphate coating, and sulfidizing have been found to be effective. Nitriding provides only marginal improvement.

At elevated temperatures, the options are few. Low-melting glasses protect also during heating but are difficult to remove and may require additional graphite lubrication of the die elements. Graphitic lubricants are simpler to apply to the die and blanks but require subsequent removal.

**Deep Drawing.** Overlays are often used with oil-base lubricants formulated with chlorinated waxes. Oxidized or phosphated coatings are successful in relatively severe drawing operations at elevated temperatures. Graphite and/or molybdenum disulfide in oil may be used.

**Roll Forming.** Oils compounded with sulfurized or chlorinated fats are used. Oil- or water-soluble polymers may also be added. Chlorinated waxes, high molecular weight waxes, or polymers soluble in oil may be effective for relatively moderate deformation.

**Spinning.** Colloidal graphite and/or molybdenum disulfide blended in oil may be used at temperatures up to approximately 205 °C (400 °F). Chlorinated wax and/or sulfurized fat in oil also may serve as lubricants. At higher temperatures, fillers such as bentonite or mica with graphite and/or molybdenum disulfide formulated into a grease are used successfully.

### Lubrication of Platinum-Group Metals

Surface contamination due to metal contact at surfaces with iron or other metals may adversely affect surface integrity and electrical resistivity. Separation of tool and workpiece by an appropriate lubricant film is critical. Platinum and palladium can be formed by most standard sheet-metal forming operations (blanking, piercing, and deep drawing). Cold welding of the workpiece to the tooling must be avoided, and therefore continuous lubricant films are important in operation. Many of the lubricants used for forming copper alloys may also be used for forming platinum and palladium. Rhodium and iridium are more difficult to form, and ruthenium and iridium are extremely difficult to form.

# Selection of Materials for Press-Forming Dies

SHEET METAL is press formed to conform to the contours of a die and punch—largely by bending or moderate stretching, or both—and die material is selected largely by the economics of how many parts that can be produced using a die. Tool materials are usually selected on the basis of providing adequate die life at minimum cost. However, the final choice may depend on availability rather than on a small difference in die life or cost.

The process of selecting the most economical material for a press-forming die is determined by a number of factors that include:

- Requirements for part production, such as quantity of parts required, allowable dimensional tolerances, size, type, thickness, and hardness of the metal being formed
- Equipment capabilities and production practices, such as lubrication methods, die clearance, machine stability, and press speed
- Tool material properties in terms of hardness, hardenability, toughness, and the size and distribution of hard particles such as carbides
- Tool design factors, such as size, thickness, and complexity (fillets, corners, holes)
- Tool manufacturing methods and maintenance (e.g., machining, grinding, regrinding, polishing)
- Tool heat treatments (hardening, stress tempering, surface treatments)

In general, the useful life of a press-forming die is determined by its wear, which is primarily affected by the length of the production run and the severity of the forming operation. The amount of wear on a given die during forming is proportional to the total accumulated distance over which the sheet metal slides against the die at a given pressure between the surfaces in contact. Thin, soft, or weak sheet metals exert the least pressure and thus cause the least wear; thick, moderately hard or strong metals cause the most rapid wear.

The two major mechanisms of die wear in press-forming operations are abrasive wear and adhesive wear (i.e., galling). Galling involves a chemical or physical adhesion of the sheet materials to the tool, and it depends on the surface smoothness and chemical composition of the die and sheet materials. The rate of wear for

each combination of work metal and die metal may vary considerably, depending on surface characteristics, speed of forming, and die lubrication. In situations in which wrinkles form in the parts, high localized pressures develop on the tools because of the ironing that takes place at these locations, and prohibitively high rates of abrasive wear and galling are almost always encountered. For more information on the factors of die wear, see the section “Wear in Shallow Forming Dies” in the article “Wear and Lubrication of Sheet-Metal Forming Dies” in this Volume.

In stamping dies, adhesive and abrasive wear are prominent mechanisms in determining tool life, and so both tool material composition and hardness are important die-life factors. Compared to blanking and piercing tools, the danger of spalling, chipping, and cracking is less significant for stamping dies. When the tool material has hard particulates for improved wear resistance, the effective hardness ( $H_c$ ) depends on the effective surface-area fraction ( $\alpha$ ) of the hard carbide phase, such that  $H_c = H_c + (1 - \alpha)H_m$ , where  $H_c$  is the hardness of the dispersed carbide phase, and  $H_m$  is the hardness of the matrix.

This article reviews the production variables that influence the selection of various stamping die materials, such as those listed in Table 1. Details on specific types of die materials are covered in sections on tool steels, cast irons, plastics, aluminum bronze, zinc-aluminum, and steel-bonded carbides. Some of these materials are also used in other tooling components besides the die. For example, guide pins, guide bushings, wear strips and plates, gibs, guide rails, guide blocks, cam-dwell wear plates, and center keys are made from steel, bronze, bronze-plated steel, aluminum bronze, sintered materials, cast iron, polymers, resins, fibers, composites, and other materials (some of which may accommodate graphite plugs for lubricating purposes).

## Selection Factors

Recommended die materials depend on a number of variables for part production, such as the required severity of deformation, part size,

sheet thickness, quantity, tolerances, and work metal. Selection factors may also depend on the type of forming operations (e.g., simple bending versus press forming). For example, simple bending dies are ordinarily subjected to less shock than other press-working tools; therefore, they can often be made of low-carbon steel, heat treated low-alloy steel such as 4140, or cast iron for low production of low-carbon steel pieces. For moderately high production, they should be made of flame-hardening grades of carbon steel, such as 1045, or flame-hardening cast iron, such as class 40 gray iron. Cam-operated dies, wiping dies, and dies used to make curved flanges (shrink or stretch) must be made of a higher grade of material. Tool steels are used for moderately long production runs.

The following sections describe factors in the selection of materials for press-forming dies. When press forming low-carbon steel, dies are made from a wide range of materials, including plastics, cast irons, tool steels, and cemented carbides. Severity of forming, number of parts to be produced, workpiece shape, work metal hardness, specified surface condition, and tolerances affect selection of the die material. Some typical examples of tool-material selection are listed in Tables 2 through 4 for various workpiece materials, with part size and configurations shown in Fig. 1. These tables are a summary (Ref 1) from observed tool performance and were based on 500 specific forming applications. They include some die materials (e.g., polyesters, phenolics) that have been largely replaced by improved materials for die applications. Details on specific types of die materials are discussed in separate sections of this article.

**Effect of Part Shape.** In simple parts (parts 1 and 2 in Fig. 1), there is limited deformation of the sheet during forming, and the die components have very low wear rates. The tooling for parts 1 and 2 consists of a punch and an upper and lower die. There is little or no sliding of the sheet over the lower die, and little movement over the punch. Large quantities can be produced in various die materials of convenient size (Table 2).

Tooling for part 3 consists of a punch and lower die (Fig. 2). In forming, the punch pushes the blank through the lower die, which results in sliding on the lower die, but there is little sliding

**Table 1** Examples of various materials used for press-forming dies

Material	Nominal composition	Comments
<b>Tool steels</b>		
W1	Fe-1.0C	...

<b>Plastics</b>		
Polyester-glass and/or powder filled	Glass filled: 50% polyester, 50% glass in the form of cloth, strand, or chopped fibers	No longer commonly used due to poor dimensional stability
Phenolic	Powder filled: metal or ceramic powder	Used for stretch forming block and some molds, but seldom used anymore
Epoxy-glass and/or powder filled	Glass filled: 50% epoxy, 50% glass (cloth, strand or fibers)	...
Nylon-metal filled	Polyamide reinforced with metal powder	Limited use
Polyurethane	...	Versatile material for low-cost die pads

on the punch. Therefore, the punch generally has ten times the life of the lower die made from the same material. However, wear and galling are expected in the areas of moderate shrinkage of this part, particularly when the part is formed on these single-action dies. For a small die and punch, the cost of steel is of minor importance, and D2 tool steel may be used for production quantities as low as 10,000. If galling occurs during preproduction trials, the tool can be nitrided. Typical materials for lower dies (Fig. 2) used in press forming small parts similar to that shown in part 3 in Fig. 1 are given in Table 3.

Tooling for part 4 (Fig. 1) consists of a punch and upper and lower die (Fig. 3). Without the upper die, excessive wrinkling would be expected at the shrink flanges. As in part 3, a less wear-resistant material is required for the punch and upper die than for the lower die, due to greater sliding occurring on the lower die. Under conditions for which the tooling was typically made of tool steel (Table 3), the tooling was in the form of inserts in a lower die made of cast iron, as shown in Fig. 3, and the punch was made of a cast tool steel. For example, a cast iron die with tool steel inserts at points of greatest wear was typical for production quantities of 10,000 to 100,000 pieces. When this part must be held to close

tolerances over lengthy production runs, tool steel inserts should be used at all surfaces subject to wear. For quantities of less than 100,000 pieces, the entire lower die was typically made of the material indicated (Table 3), without inserts. The punch was made of a less wear-resistant material, which is usually the same as the lower-die material in the first column to the left of the quantity being considered.

Table 3 may be used to select lower-die materials for parts made of sheet thicker or thinner than the 1.3 mm (0.050 in.) thick sheet used in the tables, or for parts of greater or lesser severity. For parts of greater severity or sheet of greater thickness, use the die material recommended for the next greater production quantity than the quantity actually to be made (the column to the right of the actual production quantity in the table). Similarly, for parts of lesser severity or sheet of lesser thickness, use the die material recommended for the next lower production quantity (the next column to the left of the actual production quantity).

The tooling for parts 5 and 6 (Fig. 1) consists of a punch and lower die with no upper die required, because these parts are produced by stretching rather than by shrinking of the metal along the constricted region. The metal envelops

the punch with minimal sliding and consequently produces approximately ten times more wear on the lower die than on the punch. The body of the lower die could be made of cast iron with wearing edges of tool steel, and the punch could be of a material less wear resistant than tool steel, for example, low-cost alloy cast iron. However, the same material can be used for both the punch and lower die for part 5 because of the smaller part size and minor material cost. Table 4 summarizes tool material selections for a small part of moderate severity (part 5 in Fig. 1).

In the selection of die material for larger parts of moderate severity (part 6 in Fig. 1), the critical locations are the wearing edges of the lower die. The body of the lower die would be made of cast iron with wearing edges of tool steel in instances similar to those where tool steel is indicated (Table 4). The punch for making larger parts of moderate severity could be a material approximately one-tenth as wear resistant as tool steel—for example, cast iron. For a quantity large enough to require a punch material of greater wear resistance than alloy cast iron or cast steel, a tool insert should be considered at the constricted section.

**Part Size.** For small stampings, cast or plastic dies are uneconomical unless they are made from a model already available and with only minor finishing operations required on the dies. When the cost of patternmaking is included, cast or plastic dies are usually more expensive than are dies machined from other materials. The cost of the die material is usually a small fraction of the total cost of dies for a small part, and the availability of material in such a size that would minimize machining on the dies is usually a greater factor in cost than is any other.

As the size of the part increases, cost savings resulting from minimizing machining by the use of a casting close to final size more than offsets the cost of a pattern. However, tool steel or carbide inserts must be used on high-production dies subject to severe wear and galling. The selection of both the material and the locations of the inserts should be conservative when it is important that production not be interrupted to alter the tooling. If tools can be taken out of production, gray cast iron dies may be used, with the wear surface flame hardened and inserts added later if needed because of wear on the critical surfaces.

**Work Metal.** High-hardness sheet metals wear dies more rapidly than do softer materials, but other factors, such as the presence of scale on the surface of hot-rolled unpickled steels, cause two to five times more wear. However, scaled surfaces cause less galling, which, on tool materials, may be an even more serious condition than wear, because galling or “pickup” on a die causes frequent interruptions of production forming for reconditioning of the die.

Soft brass and aluminum cause less wear and galling than does carbon steel; stainless steels and heat-resistant alloys cause more wear and galling. When galling is anticipated, it is desirable to use materials that can be treated

subsequently, if necessary, to eliminate the difficulty. Possible treatments include chromium plating of any hardened steel, the hardening of alloy cast iron, and the nitriding of or physical vapor deposition coating of tool steels containing alloy elements that provide secondary hardening during heat treatment, thus permitting them to retain their hardness through the temperature exposures in these surface treatments.

**Sheet Thickness.** Thick sheets of any metal exert greater pressure on the dies than do thin sheets of the same metal. Both abrasive wear and adhesion (galling) increase with increasing sheet thickness.

The selection tables (Tables 2 to 4) from *Properties and Selection of Metals*, Volume 1, 8th edition *Metals Handbook*, 1961 (Ref 1), are based on sheet thickness of 1.3 mm (0.050 in.). Table 5 recommends materials for dies to make parts 3 and 4 (Fig. 1) in three sizes, from sheet of four different thicknesses. The selections in Table 5 illustrate the increasing effect of galling and wear as parts are made from thicker sheets—especially parts with shrink flanges.

Table 5 deals only with die materials for forming steel parts. The forming pressure depends not only on the thickness but also on the strength of the sheet being formed. Wear and

galling are less severe with any thickness of soft metal, such as aluminum and copper alloys, than with low-carbon steel, but more severe with high-strength metals such as stainless steels and heat-resisting alloys.

**Quantity.** The number of parts to be produced is obviously an important factor. Low production quantities of simple shapes may just require plastic dies, while more severe deformation and higher production quantities need wear-resistant tool steels, nitrided steels, coated tool steel, or perhaps dies or inserts of cemented carbides with parts of extreme severity or production quantities of more than  $10^6$  parts.

**Table 2 Recommended punch material for forming a part of minimum severity**

Part (made of 1.3 mm, or 0.050 in., sheet)				Recommended punch material(a)				
Metal being formed	Requirements			Total quantity of parts to be formed				
	Finish	Tolerance, in.	Lubrication(b)	100	1000	10,000	100,000	1,000,000

(a) Where mild steel is recommended for forming fewer than 10,000 pieces, the dies are not heat treated. For forming 10,000 pieces and more, such dies should be carburized and hardened. (b) Refers to specially applied lubrication rather than mill oil. (c) Soft. (d) With inserts. (e) Heated sheet. Source: Ref 1

Adjustable inserts are often impractical for small dies. Therefore, for high-production dies working under severe wear conditions and producing parts to close tolerances, it is often desirable to use a complete insert or to make the die of wear-resistant material such as carbide, nitrided tool steel, or highly alloyed powder metallurgy (P/M) tool steel.

In materials selection for large dies, the cost of material is equal to or greater than the cost of machining. In smaller dies, the difference between the cost of the most expensive and the cheapest steels is less important than the assurance of long life without the necessity

for rebuilding tools if the quantity should be increased above original expectations, or if the die material should prove to be inadequate. However, for large dies, both the choice of tool material and the design of the dies depend on the number of parts to be produced, particularly if it is more than 1000.

**Dimensional requirements** of a part may have an important effect on the choice of tool material when the part is to be finished without restriking. If the part is to be restruck, the material used in the restriking die is of less importance, because it will usually be subjected to less wear than will the die that performs

the primary operation. A major factor in the choice between a wear-resistant material and a less costly and less wear-resistant material is the necessity for maintenance during the production run.

**Lubrication Practice.** In making parts at low and medium production (up to 10,000 pieces), it is often economical to use lubricants. Lubrication is required when zinc alloy dies are used. However, the most effective lubricants are difficult to apply and remove, and they add significantly to cost. Efficient application of lubricants is particularly difficult in high-production operations in which presses are automatically

**Table 3 Recommended lower die material for forming a part of mild severity**

Part (made of 1.33 mm, or 0.050 in., sheet)				Recommended lower die material(a)

(a) Where mild steel is recommended for forming fewer than 10,000 pieces, the dies are not heat treated. For forming 10,000 pieces and more, such dies should be carburized and hardened. Where 4140 is recommended for fewer than 10,000 pieces, it should be pretreated to a hardness of Rockwell C 28 to 32. Flame hardening of high wear areas is recommended for quantities greater than 10,000 pieces. When more than one material for the same conditions of tooling is given, the materials are listed in order of increasing cost. Under conditions for which tool steel is recommended for making part 4, the lower die should be of cast iron with inserts of wrought tool steel and the punch of a cast tool steel such as D2. For example, for 10,000 to 100,000 pieces, a cast iron die may be used with tool steel inserts at the shrink flanges; over 100,000 pieces, dies would have tool steel inserts at all wear surfaces. (b) Specially applied lubrication, rather than mill oil. (c) Soft. (d) With inserts. (e) Heated sheet. (f) Use lubrication to make 1 to 100 parts. (g) Use as inserts in cast iron body. Source: Ref 1

fed. In such operations, it is often economical to use die metals that are more costly but more resistant to galling in combination with the usually less-effective lubricants that can be applied automatically. Examples of these materials are aluminum bronze, nitrided tool steel, and carbide, which often can be used for forming low-carbon steel with only mill-oil lubrication. More information on lubricants is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

**Selection of Tool Materials for Galling Resistance.** Galling is a process of adhesive wear from the cold welding of the metal being formed to that of the dies. Galling drastically reduces the number of parts that can be made using a particular set of dies. It is caused by attempts to stretch sheet metal beyond practical limits, by inadequate lubrication, by poor tool fitting, or by rough finishes on tool surfaces.

For short and medium runs, surface-hardened hot-rolled steel dies will produce parts equal to those produced from most tool steel dies. Exceptions may be encountered in severe reductions or in forming metals that show a greater tendency to gall, such as austenitic

stainless steel. However, tool steel dies may also gall under these conditions.

When galling is encountered, the tool fit and the thickness of the metal being formed should first be checked to determine whether clearance is adequate. If clearance is considered adequate, lubrication practice should be reviewed before considering a change in die materials. Attempts to iron out wrinkles will often cause galling. Whenever possible, wrinkles should be prevented by the design of the tools.

Galling is less likely to occur if the die materials and the metal being formed are dissimilar in hardness, chemical composition, and/or surface characteristics. For example, effective combinations are aluminum bronze tools for forming carbon steel and stainless steel; tool steel tools for forming aluminum and copper alloys; and carbide tools for forming carbon steel, stainless steel, and aluminum. Aluminum bronzes have excellent resistance to galling and are desirable for dies in applications in which the best finish is required on carbon steel or stainless steel parts. However, for medium-to-high production (10,000 to 100,000 parts), the use of inserts permits easy reconditioning of worn tools.

Nitriding minimizes or prevents galling of dies made of alloy steels or alloy tool steels that contain chromium and molybdenum (e.g., D2). It is not recommended for steels that contain no nitride-forming elements, such as chromium or molybdenum. Nitrided surfaces on such steels may spall off on radii smaller than approximately 3.2 mm (1/8 in.).

Hard chromium plating usually eliminates galling of mild steel, alloy steel, and tool steel dies, and it is often used for severe duty. For operations involving high local pressures, hardened alloy steels or tool steels are less likely to yield plastically and cause cracking of the hard chromium plating. With dies for complex parts, hard chromium plating may spall off at radii smaller than approximately 6.4 mm (1/4 in.).

For some press-forming operations, dies made from tool steels other than those discussed previously may be desirable. For example, shock-resistant tool steels such as S1, S5, and S7 may be used for die components subjected to severe impact in service. H11 and H13, possibly nitrided for greater wear resistance, also may be used for such components. In press-forming operations requiring significantly greater wear life

**Table 4 Recommended lower die material for forming a part of moderate severity**

(a) Where mild steel is recommended for forming fewer than 10,000 pieces, the dies are not heat treated. For forming 10,000 pieces and more, such dies should be carburized and hardened. When more than one material for the same conditions of tooling is given, the materials are listed in order of increasing cost. Cast iron dies with inserts of tool steel would be needed for making 10,000 parts; however, the same material is recommended for punch and lower die for part 5 because of the small size and minor cost of material. Recommendations for making part 6 are the materials for the wearing edges of the lower die; body of the lower die would be of cast iron with wearing edges of the tool steel recommended; the punch could be of a material approximately one-tenth as wear resistant as tool steel. (b) Refers to specially applied lubrication rather than mill oil. (c) Soft. (d) Heated sheet. (e) Lubrication should be used to make 1 to 1000 parts. Source: Ref 1

than is routinely attained with D2 or nitrided D2, it may be necessary to specify a more wear-resistant cold work tool steel such as a high-speed steel (e.g., M2, M4, or T15) or a more highly alloyed P/M tool steel, particularly those containing high levels of vanadium. Cost generally determines the desirability of changing to an alternative material, although toughness may also be a determining factor. Costs to be considered include not only material costs but also tool fabrication costs and the cost of periodic resharping.

Dirt, grit, and fragments on the sheet can cause greater damage to nitrided and chromium-plated tools than to hardened tool steels; hard particles may cause minute spalling and small pits, especially at radii in areas of high forming pressure. When these pits in the die cause scratches on the formed sheet, the pits must be stoned out if high finish is required on the part. After such repairs have been made several times in the same area, the soft underlying metal will be exposed, and renewal of the nitrided case or the chromium plate will be necessary.

**Effect of Die Finish on Galling.** Despite the fact that, in many instances, galling can be minimized or eliminated by careful selection of die materials, die finish is an important factor affecting susceptibility to galling. The probability of galling increases as the severity of forming increases.

The influence of die finish, with other factors constant, is illustrated in the forming of a hat section where the walls of the hat were nearly perpendicular to the original blank, thus representing fairly drastic severity. The material being formed was annealed 1010 steel. The punch portion of the die was made from A6 tool steel at 60 HRC with a finish of  $0.75$  to  $0.9 \mu\text{m}$  ( $30$  to  $35 \mu\text{in.}$ ). The die ring was made from nitrided medium-carbon alloy steel having a hardness of 63 HRC and was also finished to  $0.75$  to  $0.90 \mu\text{m}$  ( $30$  to  $35 \mu\text{in.}$ ).

Both components were copiously lubricated, but after ten hits, there were indications of metal pickup, and after 30 hits the tools were removed because of excessive galling. Both die components were refinished to approximately  $0.5 \mu\text{m}$  ( $20 \mu\text{in.}$ ), after which 300 parts were produced before galling was excessive. The tools were then refinished to  $0.2$  to  $0.25 \mu\text{m}$  ( $8$  to  $10 \mu\text{in.}$ ), after which 3000 pieces were produced with no sign of galling. However, producing this high finish all over dies is costly and is not always warranted, but it should be considered when galling is experienced in severe forming. Sometimes, the use of lubricants can be minimized by improving the die finish.

## Cast Iron

Cast iron is a useful die material for forming parts larger than approximately 300 mm (12 in.). Its performance makes it suitable for use in medium production runs or short runs of large parts. When cast iron is used with inserts, it will produce greater quantities. Cast iron should have a predominantly fine pearlitic matrix with no massive carbides and a minimum of ferrite.

Graphite in gray cast iron should be of type A distribution, with a preferred flake size of 4 to 5. Flaking problems can occur with gray cast iron dies, but flaking problems in gray cast iron tooling can be eliminated by chrome plating or nitriding the tool contact surfaces. Ideally, cast tooling that is to be used to press form a coated steel should be made of cast steel or nodular (ductile) cast iron. Ductile iron has been an attractive material for stamping and drawing dies. To further improve wear resistance, laser surface modification has been used in industrial applications.

## Steels

Hot-rolled mild steel plate with carbon content from 0.10 to 0.20% is in major use as a die

Fig. 1 Parts classified into six classes based on forming severity and part size

Fig. 2 Cross section of die used to form small part of mild severity

Fig. 3 Cross section of die used to form large part of mild severity

material for short-run forming of small parts. This type of steel is not recommended without surface hardening, except for quantities of less than 10,000 parts. In addition, hot-rolled mild steel can be used for dies where straightening facilities are available for correcting distortion induced by heat treatment. Several medium-carbon alloy steels, such as 4140, are available in plate form and are useful for some types of forming dies. Such steels are generally used for lower production runs.

Cast steel is used for forming parts larger than 300 mm (12 in.) long where the shape of the part makes a casting more feasible than wrought stock. Plain carbon steel (0.65 to 0.85% C) and alloy cast steel (Fe-0.45C-1.1Cr-0.4Mo) are two commonly used compositions. Cast steel is more costly and more difficult to machine than cast iron and is more likely to gall. However, it is tougher than cast iron. One important advantage of cast steel, particularly the plain carbon grade, is its weldability. It can be rewelded with steel or hardfaced with tool steel, aluminum bronze, or other wear-resistant hardfacing alloy. Because of its resistance to galling, it is less desirable for dies used for forming carbon and stainless steels than for aluminum and copper alloys. Cast steel is also useful for restrike, flanging, and other types of dies that are less likely to gall or pick up metal from the sheet.

**Tool steels.** Cold work tool steels for press-work applications contain various amounts of carbon (ranging from 0.6 to 3 wt% C) with alloying of silicon, manganese, chromium, molybdenum, tungsten, and vanadium. Table 6 lists compositions of various press-work tool steels that have been used for press-work dies in

automotive stampings. The production methods include:

- Conventional ingot metallurgy
- Conventional ingot metallurgy with electroslag remelting
- Spray forming
- Powder or particulate metallurgy

Conventional press-work tool steels include the commonly used 5 wt% Cr tool steel (AISI A2) and 12 wt% Cr tool steel (AISI D2) for sheet metal fabrication. However, these materials (cast or wrought form) may not be the most effective choice in more demanding forming or cutting applications. The combination of toughness and hardness of D2 is relatively low compared to other types of tools, such as the martensitic grades (e.g., Carmo, Caldrie, Uddeholm Tooling AB; Diemarc, Anchor Lamina Inc.), the spray-formed grades (e.g., Roltec and Weartec, Uddeholm Tooling AB), and the P/M grades (Fig. 4).

Conventional D2 steel also is affected by a wide variation of dimensional changes after heat treatment due to the anisotropy of carbides in the microstructure. The chromium carbides have a stringerlike morphology, with inhomogeneous distribution from the surface to the bar center. The Sleipner grade is an optimized version of the D2 grade, with improved ductility compared to D2 and a smaller amount of chromium carbides (6% versus 13% for D2). This reduces the extent of dimensional change (Fig. 5).

The advantage of the martensitic die steels (such as Carmo, Diemax, and Caldrie) is better toughness, with hardness ranging up to approximately 62 HRC (Fig. 4). The Carmo/

Calmex grade (Table 6) was the first-generation version of martensitic press-work tool steels, but it has been largely replaced by new martensitic grades (such as Diemax and Caldrie martensitic grades) with better combinations of ductility and hardness (Fig. 4). Electroslag remelting also is used in the production of Diemax and Caldrie grades. This results in a significant reduction in the size of second-phase constituents and the improvement of fatigue resistance (Fig. 6).

The most significant advances in tool steels have been made in the development of powder or particulate metallurgy (P/M) tool steels. The powder process allows production with high vanadium content for more effective hardening and wear resistance from carbide formation. This production method results in a very homogeneous distribution of carbides from the surface to the center of the block and thus results in the best dimensional stability (Fig. 5). The size of defects in P/M tool steels is also smaller, which results in higher fatigue limits (Fig. 6).

Powder/particle metallurgy high-speed steels (hot isostatically pressed to full density) offer greater ease of fabrication and significantly improved toughness compared to conventional ingot-cast steels of the same compositions. New grades that could not have been produced economically by conventional steelmaking practices have been introduced through the use of P/M. Several major international manufacturers of tool steels offer a line of P/M-produced high-alloy tool steels. Most of these P/M tool steels feature a high vanadium content, to provide enhanced wear resistance through the presence of a high volume of hard vanadium carbides. The

**Table 5 Recommended materials for lower die for forming steel parts of three sizes, each in four thicknesses**

<b>For part 4, maximum dimension of 914 mm (36 in.)</b>						
0.8	0.031	Epoxy-metal, polyester-metal, zinc alloy	Epoxy-glass, polyester-glass, zinc alloy	Epoxy or polyester-glass(d), alloy cast iron, zinc alloy(d)	Alloy cast iron(c)	D2
1.6	0.062	Epoxy-metal, polyester-metal, zinc alloy	Epoxy-glass, polyester-glass, zinc alloy	Epoxy or polyester-glass(d), alloy cast iron, zinc alloy(d)	A2	D2
3.2	0.125	Zinc alloy	Zinc alloy, cast iron	Alloy cast iron(c)	A2 and D2	D2
6.3	0.250	Zinc alloy, cast iron	Alloy cast iron	Alloy cast iron(c)	A2 and D2	D2

(a) Materials recommended in above table are for forming parts from low-carbon steel; wear and galling will be less with aluminum and copper alloys, and more with stainless and heat-resisting alloys, than with low-carbon steel.  
 (b) All A2 or D2 tool steels nitrided after tryout if required. (c) Inserts of A2 tool steel are recommended for wear edges for the shrink flange. (d) At the quantity level indicated, use of inserts with these materials is required.

P/M production process permits the design of tool steels having such an elevated carbide population with minimum detriment to toughness or grindability. One of the first-generation grades is Crucible CPM 10V (Crucible Materials Corp.) (Fe-2.45C-5.0Cr-9.75V-1.25Mo), which is an air-hardened cold work tool steel designed specifically for tooling applications requiring long wear life and good toughness. This material can be a cost-effective alternative to carbide in applications in which breaking or chipping of carbide is a problem or in which the full potential of carbide is either not realized or not required

(see the article "Particle Metallurgy Tool Steels" in *Powder Metal Technologies and Applications*, Volume 7 of *ASM Handbook*, 1998).

Continuing developments in P/M tool steels include the following:

- More wear resistance with ultrahigh vanadium compositions containing 15 to 18% V with up to 30% by volume of primary metal carbide-type carbides
- Low-to-intermediate carbide volume fraction materials moderately alloyed with vanadium and chromium to optimize the toughness

properties while still maintaining good wear resistance

- High-vanadium, high-chromium compositions for wear applications that also require good corrosion resistance
- High-nitrogen P/M steels (e.g., Vancron 40)

These developments address the increasing demands of forming higher-strength sheet materials, especially for the forming of high-strength and advanced high-strength steels in the automotive sector. Higher-strength sheet materials demand tooling with more abrasion resistance, compressive strength, and chipping resistance, along with the ability to be effectively manufactured into multiple-profile sections. In addition, forming of higher-strength steels often means that tool steels have to be coated (and, in some cases, pretreated by nitriding in order to get enough support). The exception may be high-nitrogen P/M steels (such as Vancron 40), which inherently have excellent antigalling characteristics. Table 7 lists examples of tool steels and coatings for various strengths of steel sheet.

**Steel-bonded carbides** (commonly referred to as Ferro-TiC alloys, Pacific Sintered Metals) have titanium-carbide particles dispersed in a steel matrix. The steel matrix can be heat treated to obtain desirable matrix properties, and the carbides increase effective hardness for improved wear resistance. Steel-bonded carbides do not have suitable high-temperature strength for cutting-tool applications, but they have been useful as a die material. However, application of steel-bonded carbides as a die material has been reduced due to continued innovations with P/M tool steels.

## Nonferrous Die Materials

**Cemented Carbides.** For long runs, inserts of sintered carbide are now widely used, especially for deep-drawing dies. In dies of approximately 200 mm (8 in.) or less for continuous production of over 1,000,000 pieces, carbide has, in many instances, proved to be the most economical die material. Such dies have maintained size in drawing 60% reductions of more than 500,000 pieces and have made as many as 1,000,000 parts with reductions greater than 40% when the steel to be drawn was surface treated with zinc phosphate and soap. However, carbide is not superior to tool steel such as D2 in complex deep-drawing operations, such as those with reductions greater than 40% that combine drawing with coining or stretching.

When maximum resistance to galling and wear is required, cemented carbides have traditionally been recognized as the ultimate tooling materials. However, because of the high cost of these materials and their tendency to be brittle in service, carbides are frequently used only for inserts in critical die areas. These inserts are usually made of a straight grade of tungsten carbide containing approximately 6% Co binder,

**Table 6** Nominal compositions of selected cold work tool steels

Steel	AISI designation	Commercial equivalent	Composition, wt%

but higher cobalt contents can be specified to provide greater shock resistance. The aforementioned steel-bonded carbides offer greater ease of fabrication and very often can be demonstrated to be cost-effective substitutes for the more costly cemented carbides with cobalt binder.

**Stamping Punches and Dies.** The high elastic modulus of carbides combined with their ability to incorporate fine details makes them ideal tool materials for stamping punches and dies. As in many other metal-forming applications, fine-grain carbides are chosen for punches because

of their edge-retention capability and higher abrasion resistance.

**Zinc-aluminum die alloy (KirkSITE)** (Zn-4Al-3Cu-0.06Mg) is used as a forming die alloy and is capable of being sand cast to shape rapidly. It is mainly used in the construction of cast two-piece dies for forming sheet metal parts such as components for use in the transportation and aerospace industries. Two forming-die alloys are included in ASTM B 793 (Table 8).

KirkSITE can be advantageous for complicated dies that would require intricate machining and hand tooling if made of cast iron, but which can

be cast more closely with zinc. The alloy has a high pattern fidelity when cast but requires very accurate shrink patterns to minimize hand labor in finishing. It is economical only for die components at least 300 mm (12 in.) long and is most economical in dies approximately 900 mm (36 in.). In tensile strength, compressive strength, and hardness, zinc tooling alloy is inferior to other metals used in die construction.

If compound curves on the face of a stamping have no sharp creases or embossments with sharp corners, it is not unusual for zinc alloy dies to give the length of service indicated in selection Table 2 for part 2 (Fig. 1). Zinc alloy tools are particularly sensitive to surface roughness, thickness, and hardness of the sheet metal being formed. The increase of any one of these multiplies unit pressures over a small area of the die face.

In production use, zinc alloy drawing dies in double-action presses have been found to give the longest life. Contrary to conventional die-making practice, zinc alloy dies, cast to shape, are made of as few components as possible. This not only results in a lower cost, because fasteners are largely eliminated, but it adds to the simplicity and durability of the tool. Otherwise, zinc alloy tools for conventional press production are designed according to the usual practice.

Virtually all the zinc alloy in a tool can be salvaged for reuse simply by melting. For greatest economy, the user must have melting and molding facilities available; the commercial scrap value of the alloy is approximately 65% of the original cost, while remelting costs the user approximately as much as melting purchased metal.

Cycle time or press speed has a great effect on the life of zinc alloy tools. A die component moving more than 63 cm/min (25 in./min) during its working cycle is highly destructive to zinc alloy. The best results have been obtained on double-action presses that average three strokes per minute and involve drawing to a depth of more than 150 mm (6 in.). For this work, hydraulic presses are more desirable than mechanical presses. Therefore, tools made from zinc alloys have a minimum size limit. This is true because even the slowest speed of small presses is greater than is permissible with zinc alloy tooling, and the cost is excessive if a small die is run on a large press merely to suit the speed requirements. Zinc alloy dies cannot be used with unlubricated stock, because wear will be too rapid.

**Aluminum bronze (UNS C62500, Cu-13Al-4Fe)** is available in hardnesses ranging from 120 to 340 HB. The alloy has excellent resistance to galling and is desirable for dies where best finish is required on carbon and stainless steel parts.

The softer grades (120 to 270 HB) wear rapidly, particularly where wrinkling is likely to occur on the formed part. The harder grades (270 to 340 HB) wear less rapidly but are difficult to machine, drill, and tap. Where elimination of scratches is extremely important, aluminum

**Fig. 5** Dimensional changes after hardening and tempering of some press-work tool steels. bronzes should be considered, but for medium to high production (10,000 to 100,000), replacement inserts should be available to permit reconditioning of worn tools.

## Plastic Die Materials

The major uses of plastics for tooling currently include prototype parts, mockups, model duplications, spotting racks, templates, fixtures, drill jigs, spray masks, foundry patterns, core boxes, and molds and dies for producing prototype plastic and sheet metal parts. Plastic tooling offers several advantages over conventional metal tooling that include:

- Lower cost, often less than half the cost of metal tooling
- Reduced tool manufacturing time, generally a matter of hours or days rather than weeks or months
- Light weight, easily handled and used
- Easy modification for design changes and rework

Polyesters and phenolics were among the first types of plastics used in die applications, but they have been largely replaced by the harder epoxies

and improved polyurethane resins. The dimensional instabilities of phenolics and polyesters require frequent checking and modification of tools. Glass-filled polyesters are limited to low-tolerance limits, while phenolics are seldom used anymore for dies. Epoxies and polyurethanes are harder and are used more extensively.

Plastics for dies are typically filled with ceramic or metal powders for wear resistance. The selection tables (Tables 2 and 3) refer to plastics reinforced by the addition of metal powder to the uncured resin. Metal inserts may also be used in plastic tools. Although the hardness of plastics is obviously less than that of metallic die materials, plastic tools can be an economical alternative. Plastic dies are used extensively in forming, primarily for aluminum and other light alloys, but also for forming of low-carbon steels and stainless steels. Other tool applications of plastics include dies for stretch forming and bending. Plastic tooling for ironing and similar operations is not recommended, because sufficient pressure cannot be maintained for the removal of wrinkles in metals.

**Urethane** is a thermosetting plastic that has the flexibility of rubber and the hardness of structural plastics. In general, urethane offers

high load-bearing capacity, high impact resistance, low compression set, high tear strength and cut resistance, and good abrasion resistance. At the pressures used in forming, urethanes are incompressible yet deflectable solids. By controlling movement and displacement and keeping within the established capabilities of the specific formulation of urethane, long life can be maintained. There are many formulations of urethane, each having different characteristics that react quite differently in tooling.

Urethane has become a necessary and useful material in the manufacture of tools for sheet metal fabrication. The use of urethane in metal-forming operations can bring the tool engineer three distinct advantages: cost savings, improved quality, and decreased lead time. More specifically, there are five areas in which urethane may be used advantageously. Applications include:

- Pads that deflect to become female dies
- Male punches
- Wiping blocks
- Springs and pads used to apply pressure
- Wear pads, clamping jaws, and fixtures

The general advantages of urethane are as follows:

- Nonmarking characteristic eliminates tool marks, resulting poor appearance, and need for costly subsequent polishing operations.
- Automatic ability to compensate for metal-thickness variations. Urethane self-adjusts for thickness changes caused by commercial mill tolerances, as well as changes in gage of material.
- Eliminates heat treating of steel components. Many tools can be built with mild steel because of the reduction in material cost and tool fabrication time. Substantial reduction in abrasive wear
- Compensates for other variations. Automatic adjustments for various misalignments, such as ram and bolster alignment, punch and die alignment, and so on. Because part of tool construction is a flexible, self-adjusting material, less time is spent in assembly.
- Eliminates air bending. Complete pressure forming in some tools. Piece part gripped with a blankholding force prior to initial bending. Accurate and consistent flange lengths result. Reduced deformation or fluting in pressure forming throughout the stroke
- Reduces press or die damage. Urethane has the ability to absorb operator and press errors when press is of sufficient tonnage.

In order to realize the full benefit of these advantages, it is important to understand the limitations of urethane materials and design considerations, such as how pressure and deflection are controlled. Undue strain or cutting of the urethane should be avoided. Urethane behaves similarly to a solid fluid with a memory: Under force it will change its shape, but its volume will remain constant. Urethane will produce high, uniform, and continuous

counterpressure under load and, when the load is removed, quickly return to its original shape.

One of the secrets of good die design is to provide enough blankholding pressure on the downstroke and stripping or shedding pressure on the upstroke. It is frequently impossible with conventional steel springs to generate enough pressure to positively strip, shed, or hold blanks. In blanking and piercing dies, metal holdup or jamming due to double slugs is evidence of insufficient stripping or shedding pressure. In forming dies, a crown next to the bend line or blank slippage is evidence of insufficient blankholding pressure.

Another problem encountered in die design is fitting the required number of steel springs into a limited area, as, for example, in long, narrow press-brake dies. Urethane springs, strippers, shedders, and pressure pads provide more pressure per unit area than conventional springs—an ideal situation for the narrow confines in dies and fixtures.

Urethane springs, strippers, and shedders consist of cylindrical tubes that can be used

independently or to which one or two caps can be fitted. This unique combination offers:

- High pressures
- Close center distances
- Positive stripping
- Punch vibration damping
- Simple installation
- Nonmarring

Springs or cylinders are made of a tough, resilient, high-modulus grade of urethane that will withstand more than 100,000 cycles when properly applied. They are quickly installed or removed, requiring neither set screws nor stripper bolts. When fractured under load, these springs will not fly into pieces of shrapnel, thus averting damage to the die and possible injury to the worker.

**Epoxy Die Materials.** The many advantages of epoxy tools include ease of fabrication, durability, and accuracy. Epoxy resin formulations can be used to make molds and dies for forming prototype parts from sheet metal. Epoxies for tooling applications are available as casting and laminating resins with a wide range of

formulations and additives. The compressive strength and wear resistance of epoxy-ceramic systems make their use ideal for hydropress forming of metal sheet. Cast ceramic-filled epoxies also have been successfully used in drop-hammer forming of aluminum, titanium, and steel, with little or no tool wear. Drop-hammer tooling is often cast metal (usually Kirksite or steel). However, the tool-construction cost for the epoxy-ceramic hammer die (not including materials) is approximately one-fourth that of Kirksite.

# Selection of Materials for Deep-Drawing Dies

DEEP DRAWING is a process in which sheet metal is formed into round or square cup-shaped parts by making it conform to a punch as it is drawn through a die (see the article "Deep Drawing" in this Volume). In conventional deep drawing, successive draws are made in the same direction. The types of dies and other tooling used for conventional deep drawing are illustrated in Fig. 1.

It is sometimes necessary for redrawn shells to have a wrinkle-free sidewall of uniform thickness or a section in the bottom of the cup that is sharply raised, usually by forming in two operations. Such operations are difficult, impossible, or uneconomical to perform by conventional single-action drawing, but they are easily done by reverse redrawing. Figure 2 shows typical tooling for the reverse redrawing of thin-wall shells.

For economical manufacture, a drawn part should always be produced in the fewest steps possible. Ironing (that is, thinning the walls of the part being drawn by using a reduced clearance between punch and die) is almost universally used in multiple-operation deep drawing. Ironing helps to produce deep draws and uniform wall thickness in the fewest operations. Each operation is designed for maximum

practical reduction of the metal being drawn. Accordingly, the information given in this article is based on ironing reductions near the maximum of approximately 35%.

The selection of material for a drawing die is aimed at production of the desired quality and quantity of parts with the least possible tooling cost per part. In small dies (for example, those for making parts up to 75 mm, or 3 in., across), performance is the primary consideration. Material cost is a minor factor, because the cost of even the more highly alloyed tool steels is probably less than 5% of the total die cost. In dies for parts larger than approximately 203 mm (8 in.), material cost is more important, and in a die for a 305 mm (12 in.) part, it may amount to nearly one-half the total die cost, even when the tool consists of a tool steel insert in a flame-hardened alloy cast iron die.

## Die Performance

The performance of a drawing die is determined by the total amount of wear (abrasive and adhesive) that occurs during a production run. The wear of a given die material is largely determined by its hardness, type and thickness of

the sheet metal being drawn, sharpness of die radii, lubrication, and construction and surface finish of the die. The amount of wear on die radii can vary by a factor of 20 between the sharpest and most liberal radii. In drawing square cups, the formation of wrinkles at the corners, accompanied by high localized pressures, may produce prohibitively high rates of wear.

**Lubrication.** Correct lubrication of the sheet metal is essential if friction, wear, and galling are to be held to the lowest possible levels during deep drawing. In fact, deep drawing is impossible if the sheet metal is not lubricated. In actual practice, die materials are selected after trials using one or more candidate production lubricants. If excessive wear or galling occurs, a better lubricant is usually applied. For extremely difficult draws, the best lubricants are usually applied at the outset.

Table 1 lists typical lubricants used for different work metals and severities of drawing. Lubricants are marketed under proprietary names, but any supplier of lubricants can recommend commercial compounds fitting the descriptions given in Table 1. More information on lubrication in sheet forming is available in the article "Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

## Materials for Specific Tools

**Draw Rings.** Table 2 lists typical materials for draw rings (both dies and backup rings) used in drawing and ironing cups of various diameters and lengths. The data in Table 2 are for round and square cups drawn from stock 1.6 mm (0.062 in.) thick in three typical production quantities. Similar data for a large square cup and a large pan are also provided. Design dimensions for all seven parts referred to in Table 2 are given in Fig. 3. The square parts have liberal corner radii consistent with favorable die life.

Table 3 indicates the effect on material selection of changing the thickness of the sheet metal being drawn. Tool materials of increasingly greater wear resistance are required as the thickness of the work metal or the total quantity of parts is increased.

Fig. 1 Schematic showing tools used for the first draw (top) and the first redraw (bottom) in deep drawing

Fig. 2 Typical tooling used for the reverse redrawing of thin-wall shells

**Punches and Blankholders.** Typical materials for punches and for blankholders or shellholders are listed in Table 4. These materials are for punches and blankholders used in drawing and ironing round and square steel cups similar to parts 2 through 7 in Fig. 3.

More wear-resistant materials are required not only for the tools used in drawing and ironing harder or thicker stock or for those used for longer runs but also for tools used to achieve greater percentages of reduction during ironing. Table 5 lists typical tool steels used in punches and dies for short-, medium-, and long-run production at four levels of reduction in ironing. Typical materials for punches and dies used in the reverse redrawing of steel cups are listed in Table 6. In both cases, for higher production volumes of the more difficult materials or part designs, physical vapor deposition (PVD) coatings and high-alloy powder metallurgy (P/M) tool steels may be considered for longer performance or more severe operating environments than those satisfactorily handled by D2.

## Combating Specific Service Problems

Wear (most notably galling) is the most common sign of deterioration in deep-drawing tools. Wear can be reduced by selecting a harder and more wear-resistant material, by applying a surface coating such as chromium plating to the finished tools, or by using a surface treatment such as carburizing or carbonitriding for low-alloy steels or nitriding or PVD coating for tool steels. The following sections in this article are intended to supplement the basic information given in Tables 2 through 6.

**Galling.** The typical causes of galling of deep-drawing tooling are:

- Attempts to stretch sheet metal beyond practical limits
- Poor tool fit-up, with poor alignment or insufficient die clearance for the sheet thickness
- Excessive wrinkling
- Insufficient or otherwise inadequate lubrication

- Use of tool steels that are susceptible to galling without applying a surface coating to the tools or using a lubricant of superior lubricating qualities
- Rough finishes on tool surfaces

For short runs, dies made of carburized hot rolled steel or hardened alloy steel will often produce parts equal in quality to those drawn over most tool steel dies. Exceptions may be encountered in ironing to severe reductions or in drawing metals that tend to gall, such as austenitic stainless steels. These exceptions may be of little consequence, however, because tool steel dies may also become galled under the same circumstances. The longest die life can be expected when die surfaces have a very fine finish, with final surface scratches parallel to the direction of drawing. Surface treatments that provide lower friction may be beneficial. Die materials can be selected for resistance to galling on the basis of the following two criteria.

First, for parts drawn from carbon steel or nonferrous alloy sheet, the die material can be

**Table 1 Typical lubricants for deep drawing**

When more than one lubricant is given, they are listed in order of increasing effectiveness.

Metal being drawn	10% or less	Severity of drawing 25% average	50% or more
Aluminum and aluminum alloys	Straight mineral oil, 100 SUS viscosity(a); mineral oil with approximately 10% lard oil	Straight mineral oil, 200–250 SUS viscosity(a); mineral oil with approximately 15% lard oil	Mineral oil with extreme-pressure additives—sulfur and others; coating of soap or wax dried on blanks (or shells) prior to drawing (or redrawing)
Copper and copper alloys	5% soap solution; lard and soap emulsion	10% soap solution with stearic or oleic acid; lard oil and mineral oil with stearic acid	Lard oil blended with 50% mineral oil, coating of soap or wax dried on blanks or draws prior to draw or redraw
Carbon steel	Mineral oil, 250–350 SUS viscosity(a); 5% soap solution	Emulsions of lard oil, mineral oil, and sulfonated oils	Phosphate coating impregnated with dried soap or wax
Stainless steel	Castor oil and soap emulsion	Castor oil with fillers, such as mica or zinc oxide	Boiled linseed oil with mica or lithopone; phosphoric acid etch with dried soap or wax film

(a) Wearing surfaces flame hardened. (b) In flame-hardened alloy cast iron. (c) Quenched and tempered for part 4; flame hardened for part 5. (d) Flame hardened on wearing surface to not over 420 HB. (e) For drawing aluminum, copper, and steel, the tool material would be used as corner inserts. (f) For drawing stainless steel, inserts would be used for all wear surfaces.

selected without regard to galling, and then, as a finishing operation, the punch and die should be either nitrided, PVD coated, or chromium plated. If a tool steel such as A2, D2, or high-speed steel, which contain chromium, molybdenum, or 2vanadium, has been selected, the smoothly ground tools should be nitrided and then polished or buffed.

Second, for parts drawn from stainless steel or from high-nickel alloy steel, the draw ring material with the best resistance to galling is

aluminum bronze. The second choice is D2, high-speed steel, or a P/M tool steel, smoothly ground, nitrided, and polished. The third choice is alloy cast iron, quenched and tempered to 400 to 420 HB.

**Chromium plating or PVD coating** may be used to extend the service lives of tool steel draw rings. On punches, the primary function of chromium plating is to reduce frictional forces and to facilitate the removal of parts from the punch after the sidewalls have been ironed

tight to the punch. The improvement in punch life that results from such surface treatments is usually somewhat less than that attained by changing the punch material to the next-best tool steel.

For successful tool performance, chromium plating must always be deposited on a surface harder than 50 HRC; preferably, plating thickness should be 5 to 10  $\mu\text{m}$  (0.2 to 0.4 mil) and never less than 2.5  $\mu\text{m}$  (0.1 mil). This provides the required hardness and reduction of friction without excessive spalling or chipping at corners. Chromium-plated dies should be heated to 150 to 205 °C (300 to 400 °F) for a minimum of 3 h immediately after plating to minimize the possibility of hydrogen embrittlement.

**Combined operations** have found increasing use over the past 30 years. The more popular combined operations include one that combines drawing and coining and another that combines successive or tandem drawing (or ironing) operations. This latter combination is called double drawing or double ironing. Advancements in combined operations have paralleled advancements in die materials—for example, better selection of drawing steels as well as improvements in the engineering and construction of tools and especially in surface treatments such as those using zinc phosphate with emulsified soap.

These operations have increased production by doubling reductions and decreasing the number of operations, but at the same time have required capital investment in larger presses. In addition, tool steels of greater resistance to compression and heat have become necessary for drawing and ironing tools.

Double-drawing and double-ironing operations are successive operations in one tooling setup, with two dies placed in tandem so that a punch forces the cup through one die and then directly through the second die while the cup is still warm from deformation heating. The punches are longer than those used in conventional deep drawing and, because of their slenderness, are preferably made of S1 tool steel. Die materials are much the same as in single operations, except that selection is confined to tool steels such as A2, D2, or more highly alloyed tool

**Fig. 3** Seven typical deep-drawn parts. Corner radii comply with standard commercial practice. Table 2 lists typical die materials used for drawing parts of similar configuration. Dimensions given in inches

3.2	0.125	Alloy cast iron(b)	Alloy cast iron(b)	A2, D2	D2
6.4	0.250	A2	A2	D2	D2
12.7	0.500	A2(c)	A2(c)	D2(c)	D2(c)

Note: Where tool steels are recommended, they are used as inserts in flame-hardened alloy cast iron. (a) Flame hardening not necessary. (b) Wearing surfaces flame hardened. (c) In drawing 12.7 mm (0.500 in.) plate with A2 or D2 inserts, press speed is slower than for thinner stock, and the plate is phosphate coated.

**Table 4 Typical materials for punches and blankholders**

See Fig. 3 for part designs and overall dimensions.

Die component	Total number of parts to be drawn		
	10,000	100,000	1,000,000
<b>For round steel cups such as part 2</b>			
Punch(a)	Carburized 4140; W1	W1; carburized S1	A2; D2
Blankholder(b)	W1; O1	W1; O1	W1; O1
<b>For square steel cups such as part 3</b>			
Punch(a)	Carburized 4140; W1	W1; carburized S1	A2; D2
Blankholder(b)	W1; O1	W1; O1	W1; O1
<b>For round steel cups such as parts 4 and 5</b>			
Punch(a)	Alloy cast iron(c)	O1(d)	A2(c); D2(c)
Blankholder(b)	Alloy cast iron(c)	Alloy cast iron(e)	O1; A2
<b>For square steel cups such as parts 6 and 7</b>			
Punch(a)	Carburized 4140(f)	W1; O1(d)	Nitrided A2; D2(d)
Blankholder(b)	Alloy cast iron(c)	W1; O1	O1; A2

(a) Chromium plating is optional on punches to reduce friction between part and punch and therefore facilitate removal of the part. Cast iron, however, should not be plated. (b) Also applies to shellholder and blankholder. (c) Flame hardening not necessary. (d) The punch holder is flame-hardened alloy cast iron with a nose insert of the indicated tool steel. (e) For part 4, this blankholder is quenched and tempered; for part 5, it is flame hardened. (f) The punch holder is alloy cast iron with a nose insert of the indicated steel.

**Table 5 Typical tool steels for punches and dies to iron soft steel sheet at various reductions**

Ironing reduction, %	Total quantity of shells(a) to be ironed			
	1000	10,000	100,000	1,000,000
<b>Ironing punches(b)</b>				
Up to 25	W1	O1	A2	A2; S1 carburized
25–35	W1	A2	A2; S1 carburized	D2
35–50	A2	A2; S1 carburized	D2	D2
Over 50	D2	D2	D2	D2
<b>Ironing dies</b>				
Up to 25	W1(c)	O1	O1	D2
25–35(d)	W1(c)	O1	D2	D2
35–50(d)	O1	D2	D2	D2
Over 50(d)	D2	D2	D2	D2

(a) Steel sheet up to 75 HRB, or softer metals. (b) All tool steel punches should be plated with chromium 5–10  $\mu\text{m}$  (0.2–0.4 mil) thick for easier removal of the part from the punch. (c) W1 is quenched on the inside and tempered to a minimum of 60 HRC for these applications. (d) Draw rings must be inserted in shrink rings for ironing at reduction greater than 25% and for quantities of more than 10,000 parts.

**Table 6 Typical punch and die material for the reverse redrawing of steels**

Die component	Total quantity of parts(a) to be redrawn			
	1000	10,000	100,000	1,000,000
<b>Small thick-wall cups</b>				
Die and pressure ring	O1	O1(b)	A2(c)	D2(c)
Punch(d)	4140, 6150	O1, A2	D2	D3
<b>Medium and large thin-wall cups</b>				
Die and pressure ring	1018(e), 4140	4140(f), O1	A2(c)	D2(c)
Punch(d)	W1	A2	D2	D2, D3

(a) No specific finish or tolerance requirements. (b) Dies are polished and chromium plated. (c) A2 and D2 should be nitrided. (d) All punches used for making more than 1000 pieces should be heat treated to 60–62 HRC, polished, and chromium plated. (e) Carburized, hardened, and polished to a fine finish. (f) 4140 or 6150 can be used if carburized and highly polished.

steels when temperatures are high in the second operation. These more temper-resistant steels can better withstand the effects of the higher temperatures developed by increased plastic deformation of the workpiece.

**Cemented carbides.** For long runs, cemented carbide inserts are widely used in deep-drawing dies. In dies up to 203 mm (8 in.) across for continuous production of over 1 million drawn parts, carbide has often proved to be the most economical die material. Such dies have maintained size in drawing 500,000 parts with 60% reductions and have made as many as 1 million parts with reductions greater than 40% when the steel to be drawn was surface treated with zinc phosphate and soap. However, cemented carbide dies do not provide satisfactory service with inferior lubricants. In addition, carbide dies are not superior to dies made of a tool steel such as D2 in complex deep-drawing operations (for example, those that combine drawing with coining or forming and in which the reduction in drawing is greater than 40%).

The cemented carbides that are most often used for deep-drawing inserts are straight tungsten carbide grades, of normal particle size, that contain approximately 9 to 10% Co or Ni binder. Steel-bonded carbides are also used for deep-drawing tools.

**Plastics** are the most economical tooling materials for short runs, especially when a prototype part is available as a pattern for the lay-up of plastic-impregnated glass cloth facing, which is backed with chopped glass fibers impregnated with 50% resin. Among resins, polyester, epoxy, phenolic resin, and nylon have been used. The plastic dies that exhibit the longest life are those constructed so that the wearing surface is faced with glass cloth that has had most of the plastic material forced out under pressure before and during curing. Except for very short runs, plastics should not be selected as blankholder materials where burred edges of the blank slide over the plastic surface and produce severe wear or gouging.

**Zinc Alloy Tools.** Because they are relatively soft, zinc alloy tools should be used only in drawing (without ironing) small quantities of large-diameter thin-wall parts. Zinc alloy tools work best for drawing well-lubricated stock into parts 305 mm (12 in.) or more in diameter under circumstances in which wrinkling is not likely to occur.

# Die Manufacture by Electrical Discharge Machining

**ELECTRICAL DISCHARGE MACHINING (EDM)** is one of several nontraditional methods for machining. In the EDM process, metal is removed by sparks from a shaped electrode (usually graphite or copper), where the result is to make a cavity that is the mirror image of the electrode. There is no direct contact between electrode and workpiece. The sparks travel through a dielectric fluid (typically a light oil) at a controlled distance. Both electrode and work must be electrically conductive. The EDM process has several advantages when machining difficult geometries or materials with poor machinability. Cavities with thin walls and fine features are possible to machine because there is no contact between electrode and work. The removal rate is related to the melting point of the metal being machined, and so the use of EDM is not affected by the high-hardness workpieces, such as cemented tungsten carbide and hardened tool steel.

There are two basic machines for EDM:

- Plunge-type (or ram-type) EDM machine (Fig. 1), where a shaped electrode acts as a plunge in metal removal
- Wire EDM machines (Fig. 2), where the electrode is a continuously spooling conducting wire that moves like a precision jigsaw with respect to the work by a numerically controlled table

The plunge-type machine made its introduction in machining of dies, especially those made of hardened die steel and tungsten carbide in many forms, such as plastic injection molds, extrusion dies, forging dies, and die casting dies. Traveling-wire EDM differs from conventional (shaped electrode) EDM in that a thin-diameter wire acts as the electrode. Electrical discharge wire cutting is used to make stamping dies, tools for lathes, templates for use in tracer lathes, electrodes for vertical EDM, broaches, and extrusion dies. It can also be used for prototype production of parts to be made later by die stamping or Computer numerical controlled (CNC) milling. One of the most important applications of electrical discharge wire cutting is the product of progressive dies (Fig. 3), where a strip of sheet metal is advanced through the die, one station at a time.

## Fundamentals of Electrical Discharge Erosion

Electrical discharge machining is a thermo-electric process. Heat from the spark melts the metal, and bulk boiling of superheated metal ejects approximately 1 to 10% of the molten metal. As a result, the hardness or tensile strength of the metal does not have any effect on machining by EDM. This is why EDM has always been successfully applied in machining of high-strength or hardened steels.

The thermal properties of the metal determine its machinability by EDM. Copper, tungsten, and graphite are always applied as electrode materials. This can be explained by the low wear of these materials due to their excellent thermal properties.

Because 90% of the material in the molten pool of metal is not ejected at the end of the pulse, the workpiece is covered with a recast layer 1 to 30  $\mu\text{m}$  (0.04 to 1.2 mils) thick. Sometimes, this layer is desirable, because its hardness and roughness hold lubricating oils. However, in some applications, the recast layer has to be removed in order to avoid surface fatigue.

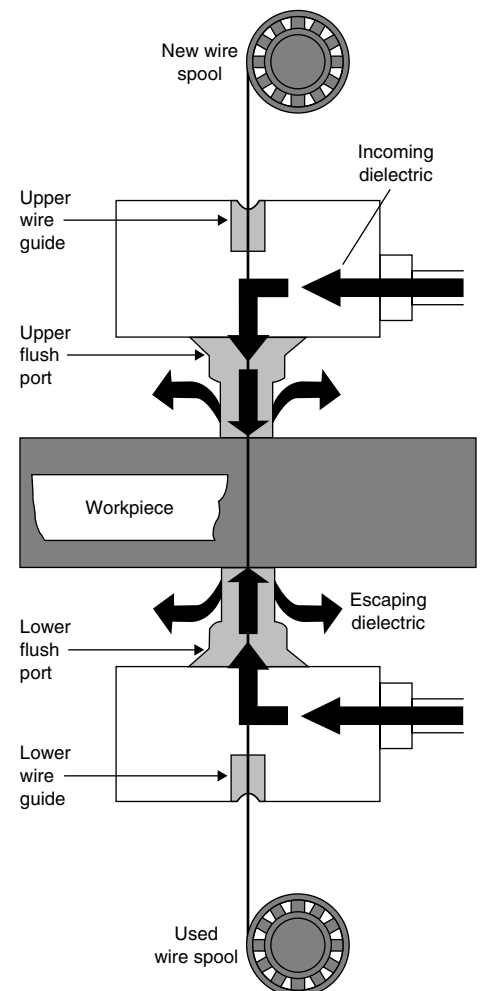

**Fig. 1** System concept of plunge electrical discharge machining with a shaped electrode

**Setting of an EDM Machine.** The dependent parameters in the EDM process are:

- Metal-removal rate,  $V_W$  ( $\text{mm}^3/\text{min}$ )
- Relative electrode wear,  $\theta$  (%):

$$\theta = \frac{V_E}{V_W} \cdot 100$$

**Fig. 2** System concept of wire electrical discharge machining process

where  $V_E$  is the electrode-removal rate.

- Surface finish,  $R_t$  (peak to valley,  $\mu\text{m}$ )
- Thickness of recast layer
- Gap between electrode and workpiece
- Radii of corners and edges

These parameters are dependent on the following independent parameters:

- Electrode material
- Electrode polarity (+ or -)
- Pulse current,  $i_f$  (A)
- Pulse duration, or on-time,  $t_j$  ( $\mu\text{s}$ )
- Pulse interval time, or off-time,  $t_o$  ( $\mu\text{s}$ )
- Average voltage or working voltage,  $U$  (V)
- Average current or working current,  $I$  (A)
- Working current density,  $I_d$  ( $\text{A}/\text{cm}^2$ )
- Open-gap voltage,  $U_o$  (V)
- Type of dielectric
- Flushing mode

**Dielectric-Fluid Unit.** Dielectric fluid is pumped through a filter from a container (100 to 200 L) to the electrode or workpiece. Pressurized flushing through the electrode results in a conical hole in the work because sparks also occur at the sides of the electrode due to the excess of debris in the side gap. When vacuum flushing through the electrode or through the workpiece is used, a straight hole is obtained.

## Principles of Electrical Discharge Machining

An electrode, which serves as a cutting tool, and a workpiece are placed face to face with very little clearance (several to several tens of micrometers) in a dielectric fluid (kerosene-based oil specially made for EDM is generally used). Current pulses are continually supplied to the clearance from a pulse power supply (approximately 60 to 300 V) to provide transient arc discharge (discharge retention time: 0.1  $\mu\text{s}$  to 8 ms) at a high frequency so as to remove workpiece metal with a very dense energy provided by the discharge. Figure 4 shows the five-step process from spark discharge, through metal machining, to the original cool state.

It sounds as if it takes a long time for steps 1 to 5, but actually the entire process is completed in  $1/50$  s even for rough machining, which is the slowest among the machining processes. This discharge between the entire surface of the workpiece and that of the electrode is repeated several tens to several hundred thousands of times for machining. If, therefore, electrodes are made only of such easily machinable materials as copper and graphite, workpieces can be machined highly accurately to shapes corresponding to the electrode shapes, regardless of workpiece hardness and machinability.

**Surface Roughness, Electrode Wear, and Machining Speed.** Because EDM is performed by accumulation of single discharges, the amount machined, machining speed, clearance,

and surface roughness increase as the single-discharge energy increases (Fig. 5). The amount of single-discharge energy depends on the single-discharge peak current (power setting) and time (pulse width). Single-discharge energy is large if the power setting and pulse width are large, and small if both settings are small. To obtain the desired surface roughness, the power setting and pulse width must be elected

from the combinations that have the same single-discharge energy:

- Large power setting and small pulse width
- Small power setting and large pulse width
- Power setting and pulse width intermediate between the previously listed combinations

Figure 6 shows methods of selecting power setting and pulse width for the same surface

Fig. 3 Progressive die cut by traveling-wire electrical discharge machining. Courtesy of Progressive Tool Company

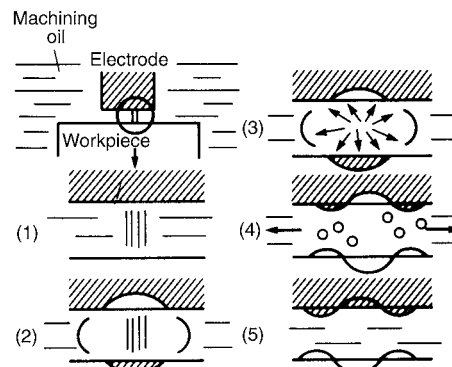

Fig. 4 Process through which metal is machined by spark discharge and oil pressure. (1) When the electrode approaches within several micrometers of the workpiece, a spark is generated at a point of the shortest distance and immediately becomes a fine arc column, or a flow of electrons at high current density, hitting the workpiece at one point. The electron flow generates heat at this point, to a temperature high enough to melt tungsten, which has a high melting point. At the same time, ions, which are generated by collision of the electron current with the dielectric fluid, heat the electrode. (2) The heat vaporizes the dielectric fluid around the flow. (3) The pressure applied to the melted workpiece and electrode is small compared with the entire surface of the workpiece and electrode but is very large per unit area. (4) Molten metal from the workpiece is blown away into the dielectric fluid as small round blocks. The remaining portions on the edge form protrusions on both the workpiece and electrode. The protrusions become discharge points for later discharge. (5) Cool dielectric fluid flows into the hollow where molten metal has been blown off, removing the residual heat from the hollow.

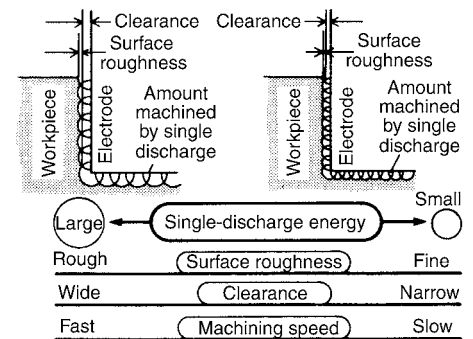

Fig. 5 Relations between single-discharge energy and machining characteristics

roughness and the relationships among methods, machining speed, and electrode consumption.

## Principles and Features of Orbital-Movement EDM

This machining method provides better performance than that obtainable with conventional EDM, because orbital-movement machining controls the  $x$ - and  $y$ -axes in addition to the  $z$ -axis.

**Improvement in Machining Shape Accuracy.** Orbital-movement machining prevents loss of accuracy in the side-surface direction (uneven clearance, taper, intermediate protrusion, or uneven surface) so that the entire surface can be machined evenly at any desired clearance (Fig. 7).

**Less Electrode Wear.** Because orbital-movement machining finishes a shape by machining in the side-surface direction, the electrode wear is not concentrated on the edge, as in conventional machining methods, and consequently, the effect of electrode wear is much smaller than in conventional machining methods (Fig. 8). The result is a finer surface, decreased spark-hardening layer, and increased machining speed.

**Improvement in Finish Machining Speed.** Discharge area is wide, and sufficient machining current can be supplied (area effect) because machining is performed in both the bottom and side-surface directions at the same time. Orbital movement also helps to remove machining chips more quickly, preventing generation of arcs (Fig. 9).

**Reduction of Electrode Manufacturing Man-Hours.** Because any values can be selected for machining dimensions by setting the orbital-movement amount, two or more electrodes of different sizes for roughing and finishing are not required. An electrode manufacturing process using only one type of electrode suffices (Fig. 10).

**Taper Machining with Straight Electrode.** Taper machining can also be performed with a straight electrode, as an orbital-movement machining application. Examples of taper-machining capabilities include machining of different top and bottom shapes or top and bottom radii, machining punch and die simultaneously, machining sharp edges and corner radii, and angle alteration.

a voltage between the wire electrode and workpiece, while flooding the cutting areas around the wire electrode with a dielectric fluid. Wire (normally brass) is used once. Servo control of the machine is similar to that of vertical CNC machines. Flushing problems or workpiece distortion sometimes make it necessary for the wire and work to separate. The controller must ensure that the separation takes place along the path previously cut. Work thickness capacity of 150 mm (6 in.) is average, with some machines capable of up to 420 mm (16.5 in.).

Wire EDM machines have at least two controlled axes ( $x$  and  $y$ ), which only allow vertical cuts. Most machines allow simultaneous four-axis control using two auxiliary horizontal axes (called  $u$  and  $v$ ). With four-axis control, the machine can tilt the wire to produce tapered work. Independent four-axis controls (machines with controlled vertical and rotary axes) are also available to allow production of top profiles that are independent of bottom profiles. Constant wire tension is maintained. The tension must be high enough to keep the wire straight in the cutting zone but not high enough to break the wire. The right tension is a function of the wire material and diameter. Wire guides are made of a hard material such as sapphire or diamond to minimize wear. The guides are required to keep the wire vertical, which is necessary to maintain straight sides on the workpiece. Hydraulic servo mechanisms are not used in wire EDM. The servo motion is done with direct-drive alternating current servo motors, direct current servo motors, or stepper motors. The monitored quantity is the voltage between the wire and the workpiece.

Flushing is provided by nozzles at the upper and lower wire guides, with the stream of dielectric being coaxial with the wire. Swarf is removed by filtration and settling. The dielectric fluid is typically deionized water of high insulation resistance, so that the electrode discharges electricity through the deionized water. The discharge forms an arc column at the shortest

**Fig. 7** Improved side-surface accuracy in orbital-movement machining. A: Conventional machining (two electrodes). B: Orbital-movement machining (one electrode),  $R = 50 \mu\text{m}$  (2 mils). C: Orbital-movement machining (two electrodes),  $R = 50 \mu\text{m}$  (2 mils)

**Fig. 8** Relationship between machining direction and shape of electrode wear

## Wire EDM

Wire electrode discharge machining brings a thin wire electrode (made of brass, tungsten, or copper wire) to a workpiece and impresses

**Fig. 9** Comparison in machining speed between orbital-movement machining and nonorbital machining. (a) Orbital circular movement;  $F = 50 \text{ mm/min}$ . (b) Orbital circular movement; radius  $100 \mu\text{m}$

distance between the wire electrode and workpiece surfaces and heats both sides locally, melting them with thermal energy, as shown in Fig. 11(a). At the same time, the insulation water around the wire electrode is heated to vapor state and expanded rapidly to create a local explosion (Fig. 11b). The explosion pressure turns molten metal into fine metal particles, which are carried away in the water. The workpiece and wire electrode surfaces are then cooled to leave a dent, as shown in Fig. 11(c). Because the discharge and metal removal are performed repeatedly at a very high frequency, the dent on the workpiece surface grows gradually to form a groove along the wire electrode shape as the wire electrode is fed at increasing speed.

**Workpiece Thickness and Machining Speed.** Wire electrode discharge machining defines machining speed as sectional area of machining per unit time:

$$\begin{aligned} \text{Machining speed (mm}^2/\text{min)} &= \\ \text{Machining feed speed (mm/min)} & \\ \times \text{Workpiece thickness (mm)} & \end{aligned}$$

The machining speed of a wire electrode discharge machine is almost proportional to the machining current between the poles, as in general-purpose die-sinking electrical discharge machines. In other words, a higher peak current and shorter rest time increase the machining speed.

A greater workpiece thickness makes the machining surface area larger in the advance direction, and the area effect works effectively to improve the machining speed.

Because the peak current value is selected by machining setting, peak current is higher and thus machining speed is faster if the machining setting is larger. A larger machining setting, however, causes greater surface roughness. Figure 12 shows the relation between machining speed and workpiece thickness.

**Machining accuracy** in wire electrode discharge machining includes uniformity, straightness, and shape accuracy of machining groove width. Normal accuracy is approximately  $\pm 0.013$  mm ( $\pm 0.0005$  in.). Special measures

such as multiple passes and precise temperature control are used for a higher accuracy of  $\pm 0.005$  mm ( $\pm 0.0002$  in.). Power settings may be decreased with each pass for improved surface, as with vertical EDM.

**Machining Groove Width and Machining Feed Speed.** Dispersion in machining groove width is all equal to that in the final dimensional accuracy because half of the width is considered as an offset value and left in the inside or outside of a size specified in the drawing to obtain the desired dimensions when a workpiece is machined.

Figure 13 shows the relation between machining groove width and machining feed speed. Optimal feed occurs when the electrical condition of the machining power supply is altered greatly using a mean machining voltage constant-control system. As shown in the figure, optimal feed creates an overall change in the machining groove width of approximately  $15 \mu\text{m}$  (0.6 mil) even if the electrical condition

is changed to significantly alter the machining feed speed.

Figure 14 shows the relation between machining groove width and mean machining voltage in a constant-feed/speed system. The relationships at two machining feed speeds,  $F 1.4$  and  $2.4$  mm/min, are shown with the electrical condition of machining power supply altered for each speed. As illustrated in the figure, the

Fig. 12 Relation between wire electrode machining speed and workpiece thickness

Fig. 13 Relation between machining groove width and machining feed speed in wire electrode discharge machining

Fig. 10 Comparison of electrodes for conventional and orbital-movement machining processes

Fig. 11 Schematic showing principles of wire electrode discharge machining. See text for details.

Fig. 14 Relation between machining groove width and mean machining voltage in a constant-feed/speed wire electrode discharge machining system

machining groove width varies 32 to 35  $\mu\text{m}$  (1.3 to 1.4 mil) with the changes in the electrical condition at either speed in the constant-feed/speed system. In other words, changes in mean power greatly affect changes in groove width.

Consequently, the optimal speed system enables changes in electrical condition and machining feed speed with less effect on machining groove width than the constant-feed/speed system.

**Second cut** is a finishing process similar to that of a die-sinking EDM. It is performed as follows: the primary machining (first cut) is made on a workpiece, leaving a finish allowance; the electrical condition for the finish allowance is switched to finish condition, decreasing the offset amount gradually so as to perform two or more surface-removal passes for finishing. As in general-purpose EDM, however, increased speed causes greater surface roughness and corner rounding, which results in lower dimensional accuracy. It is the second-cut process that solves these problems; this process provides high accuracy and good surface finish. Figure 15 shows the relation of the number of second-cut passes to machining accuracy and surface roughness. The figure indicates that the required times for one-pass and two-pass machining have a ratio of approximately 1 to 0.3 (the latter being approximately three times shorter than the former). Two-pass machining also gives higher machining accuracy, if, for example, a 40 mm (1.6 in.) thick SKD-11 workpiece is to be finished at a surface roughness of approximately 10  $\mu\text{m}$   $R_{\text{max}}$ .

**Examples of Applications.** Three examples of applications of wire electrode discharge machining, together with the advantages realized from use of the process, are:

- Plastic molding dies, for which a major reduction in machining time can be achieved with the integral machining of sirocco fans.
- Progressive dies for stepping-motor cases, for which the process provides major cost reductions with significantly shortened delivery times.
- Dies for printed-circuit boards, for which the automatic wire-feed option eliminates burrs—an advantage in unattended operation.

### Effect of Recast Layer on Surface Integrity and Fatigue Life

Electrical discharge machining is known to have a large detrimental effect on fatigue strength. The nature of the EDM process, which entails removal of metal by melting and vaporization of the metal surface, inherently induces very large residual stresses that are tensile in nature and hence detrimental to fatigue resistance. The rapid cooling of the surface layer by the dielectric also results in surface and sub-surface cracks and microcracks. Such cracks also tend to propagate due to the stress-concentration

effect, and, under cyclic loading, fatigue failure occurs prematurely.

Such deterioration in fatigue strength due to EDM has necessitated subsequent surface-layer-removal operations for heavily stressed components or those subjected to cyclic loads. Most users remove the recast layer to restore the fatigue strength.

Figure 16 shows the nomenclature used to define the various layers on the surface of a component machined by EDM. The recast layer is a layer of metal that was in the molten state and that solidified on the surface. The heat-affected zone is a layer, below the recast layer, that has been subjected to elevated temperatures sufficient to alter its mechanical and metallurgical properties. Both layers together are known as the altered metal zone.

### EDM Electrodes

Although EDM electrodes can be made of many different types of metals, graphite electrodes have emerged as the best EDM cutting tools. This superiority stems from the excellent electrical and thermal properties of graphite, which together bring about good EDM metal-removal rates and relatively low electrode wear. The importance of electrode wear is evidenced in the fact that the EDM process is frequently referred to as spark erosion. It is inherent in the process that this erosion occurs not only on the workpiece but on the electrode as well (although at a lower rate). If EDM parameters are chosen to keep electrode wear in the minimal range (referred to in the industry as no-wear machining conditions), the ratio of wear between the workpiece and the electrode can still be roughly 100 to 1, that is, machining 25 mm (1 in.) from the workpiece removes 0.25 mm (0.010 in.) from the electrode, and seldom uniformly. Consequently, an electrode can be used for only a

Workpiece: SKD-11, 40 mm thick

Electrical condition: Standard second-cut condition

**Fig. 15** Relation of number of second-cut passes to machining accuracy and surface roughness in wire electrode discharge machining

few workpieces (and sometimes not even one completely) before it is worn out of tolerance.

Because electrode wear is one of the major limitations of this process, EDM parameters are set to these no-wear settings to conserve the electrode as much as possible. However, although such machine settings can prolong electrode life, they prolong EDM time as well. To achieve the maximum efficiency from the EDM process and to make it economically justifiable on more machinable materials, the cost and inconvenience of forming the electrodes consumed as tools in EDM is important. At present, the EDM process generally affords the user the simple privilege of conventionally machining the electrode material instead of the workpiece material.

Conventional machining of an electrode is pretty much the same as machining of any other workpiece, except, of course, that the electrode material is probably more machinable. In

**Fig. 16** (a) Surface layers on a component machined by electrical discharge machining (EDM). (b) Fractured samples showing the fractured edges and the recast layer

general, however, conventional machining of new electrodes (or remachining of used electrodes to re-establish dimensions reduced by wear, after some use) involves significant time and cost. The time required, in relation to the time needed for conventional machining of the workpiece itself, depends primarily on the machinability of the workpiece material. Thus, if accurate forming of electrodes were made drastically easier, electrode wear would be less critical and EDM parameters would be less constrained, permitting higher cutting speeds with no sacrifice in accuracy or finish.

**Orbital Grinding and Ultrasonic Abrading Techniques of Graphite EDM Electrode Forming.** Two systems—orbital abrasive grinding and the proprietary SoneX process (ExOne Co.)—are specifically designed for machining of graphite electrodes. Both of these methods use low-amplitude grinding motions to form the total electrode shape and are a full order of magnitude faster and more convenient than conventional machining.

*Orbital abrasive grinding* is a method in which two horizontal platens—one holding an abrasive forming tool and the other a graphite electrode block—are oscillated in a precise orbital path with respect to each other. While orbiting, the two platens are brought together, causing the full three-dimensional shape of the abrasive forming tool to be ground into the graphite electrode material. This cutting action occurs simultaneously over the full surface of the abrasive forming tool, producing surface finishes on the electrode that are much finer than those produced by profile milling. The flow of a flushing fluid through the machining gap, combined with frequent vertical reciprocation between the platens, washes away the abraded graphite as fine particles.

The amplitudes used by an orbital abrader range from 0.25 to 6.25 mm (0.010 to 0.250 in.), with 1.5 to 2.5 mm (0.060 to 0.100 in.) being the typical amplitude range at speeds of 1000 to 1200 oscillations per minute.

Orbital abrasion produces an electrode form that is orbitally undersized by the amount of the orbit amplitude. If the abrasive forming tool is the same size as the form to be EDM'd, the resulting electrode is suitable for orbital (sometimes called planetary) EDM. In orbital EDM, rather than following the conventional EDM technique of simply sinking the electrode straight into the metal workpiece, the electrode is instead orbited while machining the workpiece (just as in orbital abrading, the electrode is typically orbited into the abrasive forming tool). When an orbitally abraded forming tool is used, the EDM orbit is normally set to be the same as the abrading orbit was when the electrode was formed, minus the amount per side needed for the EDM overcut (i.e., the spark gap). Orbital EDM can offer dramatic benefits in cutting speed, surface quality, and precision when compared with the conventional EDM technique.

When an orbitally abraded electrode is used in conventional, straight-sinking EDM, an on-size

electrode must be produced by using an abrasive forming tool that is oversize by the amount of the orbit amplitude to be used in abrading the electrode.

The actual forming tool for the orbital abrader, when producing electrodes for use in orbital EDM, can simply be an EDM'd form itself, because a fairly rough EDM surface can easily abrade graphite. Alternatively, an abrasive forming tool may be formed by a technique of casting from a reverse model of the form to be EDM'd.

*SoneX Process.* The second electrode-forming technique, SoneX, also uses a low-amplitude oscillating motion, but as a vertical vibration and not as a horizontal orbital oscillation. The amplitude of tool motion is much lower, typically 0.025 mm (0.001 in.), and the frequency is very much higher, typically approximately 20,000 cycles/s; hence, it is called ultrasonic abrading. In this technique, a non-abrasive forming tool attached to a special toolholder/sonic transducer combination (often called a sonotrode) is vibrated longitudinally at the resonant frequency of the sonotrode/forming tool. At the same time, an abrasive-filled fluid is flushed through the gap between the forming tool and the workpiece. Sometimes, it is desirable to attach the graphite electrode blank to the vibrating sonotrode and then feed it into the stationary forming tool. In either case, a gentle machining action is produced as the sonotrode vibrates the fine abrasive particles flowing throughout the machining gap and propels them against the graphite electrode workpiece material. These shaped vibrations, resonant with the forming tool, cause a shape that is the exact reverse of that of the forming tool to become abraded into the electrode.

SoneX ultrasonic electrode forming relies on a vertical motion—the constant low-amplitude, high-frequency acoustic vibration produced by the sonotrode—to perform the required machining. The forming-tool replica produced by ultrasonic grinding will have an overcut (controlled by the abrasive particle size) that usually can be made to coincide with the expected EDM overcut.

What is particularly dramatic about this technique is its ability to produce intricately detailed electrodes with sharp internal corners and excellent surface finishes. Even very precise or subtle configurations can be produced. Very low machining forces permit manufacture of fragile electrode designs that are preserved by the gentle ultrasonic abrading action—an action in which literally thousands of tiny vibrating abrasive particles serve as the cutting tools. SoneX ultrasonic electrode forming can produce electrodes that once were simply too intricate to be machined or that, if producible at all, could be formed only by laborious hand engraving.

These two new electrode-forming techniques are based on a similar theory of low-amplitude oscillatory abrading action, although they differ somewhat in application, with each approach

offering its own strengths. Orbital abrasive grinding uses a low-amplitude horizontal orbiting motion to machine an orbitally undersized reverse impression of the forming tool into the workpiece. This system is suitable even for very large electrodes. One consideration to keep in mind, however, is that, due to the orbital motion, some details (particularly internal corner radii that are smaller than the orbit amplitude) may be lost.

On the other hand, ultrasonic abrading uses an even lower-amplitude and higher-frequency longitudinal vibration to accomplish a similar task. Ultrasonic abrading is often better suited to the forming of small or delicate electrodes. The ultrasonic abrader forming tool imparts its shaped vibrations to the abrasive grains in the fluid flowing throughout the machining gap. These tiny vibrating particles, not the forming tool, perform the actual machining. The SoneX system is limited to electrodes under 100 mm (4 in.) in diameter and has some other limitations in producing certain shapes and depths.

Despite their different mechanisms (and the particular benefits associated with each), these two machining techniques are strikingly similar in their overall effects on the EDM process: the extremely efficient production of graphite electrodes with accurate dimensions and excellent surface finishes allows the use of faster EDM parameters (such as in negative polarity) that have previously been dismissed because of their increased tool wear. Both techniques can use the original EDM'd part itself as the forming tool or, alternatively, can use an epoxy forming tool cast from a model of a production part. Because of their improved machining speed and accuracy, both the orbital abrasive grinding and SoneX systems can machine and re-dress worn electrodes with little of the expense and time normally spent in conventional machining of electrodes. The final result is that these improvements in electrode forming provide for a more economical EDM process, particularly when multiple electrodes are required.

## Electrochemical Machining

Another technique that improves the speed and quality of machining of dies is electrochemical machining (ECM). In this process, a low-voltage, high-amperage direct current electrochemically dissolves the die form into the workpiece, regardless of workpiece hardness, in an electrolyte made of a salt and water solution. Compared with EDM, ECM produces surface finishes that are generally much finer and contain no recast layer. There is also little electrode wear.

On the other hand, ECM equipment is expensive, partly because of the special materials that must counteract the corrosive nature of the electrolyte.

Another limitation is the expense of generating a tool (cathode) that will accurately form a cavity to close dimensional tolerances. An

ECM cathode will not produce a form that is its exact geometric opposite, because the overcut across the machining gap will vary due to several factors, including:

- Variations in the flow speed of the electrolyte throughout the gap, particularly at “dead” spots or eddy currents
- Changing electrical conductivity of the electrolyte due to temperature increases (the

current flow in the gap heats the electrolyte by electrical resistance) and to changing hydroxide concentrations (the metal removed as the electrolyte flows across the gap becoming, almost instantly, a metal hydroxide that changes the electrolyte conductivity as well)

Because of these factors, tool development for ECM work becomes increasingly expensive as tolerances become closer. However, for high-

volume tool and die applications with moderate tolerances, this expense may be justified.

# Progressive Dies

A PROGRESSIVE DIE incorporates several individual work stations where successive operations are performed on a part. Frequently, all the operations required to complete the part are incorporated in a single die.

Progressive dies are also called “cut and carry dies,” “follow dies,” or “gang dies”—labels descriptive of the operational aspects of such dies. Each workstation performs one or more distinct operations on the part. The part is carried from station to station by the stock strip to which it is left attached throughout the operation. As the part moves forward, it is positively positioned in each workstation until it is completed and cut out of the strip in the final operation.

## Factors in Selecting Progressive Dies

The operations performed in a progressive die could be done in a series of dies involving the use of several presses, but this would require a good deal of handling to move the parts from one press to another. Although this multiplicity of machines and materials handling would seem to indicate that progressive dies should always be used, there are a number of factors that must be considered before the feasibility of using a progressive die can be established. Perhaps the most important of these factors is the part itself. Progressive dies are more or less restricted to the production of small stampings, including hubcaps and headlight shells. Handling problems often preclude the use of progressive dies for large parts.

**Increase in Productivity.** The primary purpose of using a progressive die is to increase productivity—that is, to achieve greater production at the same or less cost in manpower, materials, and machines. Thus, all the factors related to an operation must be considered to determine whether a progressive die will meet these objectives.

**The costs** involved in the use of progressive dies are frequently a decisive factor in their selection. Progressive dies, due to their complexity, are generally very expensive to build. This expense must be weighed against anticipated savings in manpower, materials, and machines. The progressive die process and alternative processes such as line-die, multislide, or transfer processes must be compared to determine at what piece price each can produce

a given part. If there is enough advantage in using a progressive die, the construction cost may be justified by a decreased piece price.

**The production volume** of the part to be produced is a most important factor in determining whether to use a progressive die. This matter ties in closely with the subject of overall cost. Frequently, the die itself will be the most expensive item in a progressive operation. The cost of the die will ordinarily have to be amortized within the limits of the production run. For this reason, the use of progressive dies is generally restricted to high-volume parts. Except in rare instances, the cost of the die would prohibit progressive operations for low-volume parts. Some low-volume work may be done on progressive dies where only a few operations (two or three) are involved and the die construction is very simple.

**Press Availability.** Another factor involved in determining the selection of a progressive die is the availability of a press. Presses for progressive dies usually require wide beds to accommodate the multiple work stations of the die. The size of bed is, of course, dependent on the size of the part to be made.

**Stock Requirements.** Because of certain limitations presently inherent in progressive die operations, the material required to make the part is also a factor in determining whether to use a progressive die.

The progressive die uses a mechanical system to pilot the strip or coil stock into the various workstations. If the stock for a given part is too thin, it will wrinkle or buckle while being fed into the press. The wrinkles formed will result in scrapped production. As a result, progressive dies can be used only with stock that is of heavy enough gage to permit proper piloting.

Restrictions with respect to heavy-gage stock are also encountered in the use of progressive dies. These restrictions are related to the problem of supplying straight, well-leveled stock to the die. Roller levelers or stock straighteners are usually used. If the stock is too heavy; however, proper results may be impossible to achieve. If wavy or uneven stock is introduced to the die, scrapped or damaged parts will generally be made. As a result, there are restrictions on the thickness of stock that can be used in progressive dies.

Because progressive dies depend on a carrier strip to move the part through the workstation,

coil stock generally must be used. Some progressive operations may be done with strip stock, but coil stock is preferred for greatest efficiency. Single blanks cannot be accommodated in progressive dies, although they are used for progressive work in transfer-type operations where separate die stations and transfer devices are employed. Therefore, where progressive dies are contemplated, the availability of coil stock should be ascertained well in advance of the beginning of die construction. The proper size of coil and proper gage of steel should be determined and ordered from the steel supplier.

## Strip Development for Progressive Dies

To determine the best coil size to use for a progressive die, a strip development should be made. A strip development is a visual representation of the operational steps a part will go through from start to finish in a progressive die. It provides a tentative picture of the position and relationship of each workstation in the die and indicates the distance between each station. From this development, the process engineer determines how wide the strip should be (Fig. 1–7).

## Purposes of Strip Development

In addition to providing a means of determining coil size, numerous other important purposes are served by a strip development.

**The practicality** of using a progressive die to make the part in question is one of the first considerations in using a strip layout. By obtaining a visual representation of the operations involved, it is possible to determine whether it is practical to use the progressive method. In some cases, an excessively complex die design may be required. In others, the operations involved may be too difficult. In these cases, planning would revert to the use of line dies. Layouts that are too long for available presses, are too wide, or require too much tonnage are typical of the unfavorable conditions that may be uncovered in the study of a strip development.

**Material Economy.** A strip development also provides a means of arriving at the most economical use of material. Economy of

material usage must be considered so as to obtain fully the possible reductions of manufacturing costs through use of progressive dies. The strip development should be studied with a view toward using the narrowest possible carrier strips consistent with requirements for producing parts of acceptable quality. It may be discovered that carrier strips outside the part are most feasible. On the other hand, some parts may be carried most effectively by a center strip. In many cases, experimental layouts indicate that the greatest economy can be achieved by running two parts at a time—a procedure that usually provides surer control of the part through the die. This procedure yields more balanced conditions with respect to the thrust of the ram. Often a right-hand and left-hand part can be run together. This

gives a twofold advantage by eliminating separate manufacturing costs while contributing to a better die. The layout should be studied with a view toward reducing scrap production as much as possible. This may call for changes in the original strip layout. Such changes should be discovered early in the die-development process in order to procure the proper size of stock in time for the beginning of production. The objective for every part should be to obtain a “no-scrap” layout. This, of course, is a physical improbability for most parts, but adopting this objective will lead to the maximum scrap reduction.

**Part-Design Changes.** Study of a strip development may also indicate changes in part design. In progressive die work, some notching

and piercing is usually done in the first stations to allow for forming. When the part is cut out of the strip in the final station, the cutoff punch must line up with one or more of these previously cut notches. To avoid “slivers” and to obtain extreme accuracy in strip location, the cutoff line is usually designed to meet the radius of the notch. To obtain this desirable condition, it may be necessary to change the design of the part to permit the cutoff line to line up with the notch.

Changes in part design may also provide an opportunity to achieve greater material economy through better nesting of parts in the strip. The full effect of any design change should, of course, be studied before such a change is suggested.

**Operational Sequences.** Sequences of operations that will produce the part most effectively are often determined through analysis of the strip layout. While rigid rules for sequencing operations cannot be formulated, there are principles that should be followed. The requirements for making the part within cost limitations will be the guiding factors in arranging the layout.

All holes that can be pierced without danger of deformation or mislocation should be pierced prior to forming. Some of these holes should be selected as piloting points for locating the part in subsequent operations. Where no suitable holes are available, it may be necessary to pierce pilot holes in the carrier or in the scrap. Holes should be as far from the center axis as the width of the strip will allow. This is particularly important in a strip with a center carrier. Pilot holes designed in this way will prevent mislocation of the part as it advances in the die. They will also prevent shifting of the part in forming operations.

The part should be blanked out following the creation of pilot holes. This should take place in the same station where piercing is done or in the station immediately following.

Forming follows the blanking operation. Where possible, all forming should be done in one station to avoid inaccuracies that are apt to occur from relocating a partially formed part in a subsequent station. All holes that would suffer deformation if made previously should be pierced after forming. Any restrike or additional forming operations should be done just prior to the final station in which the part is severed from the carrier strip.

### Principles of Strip Development

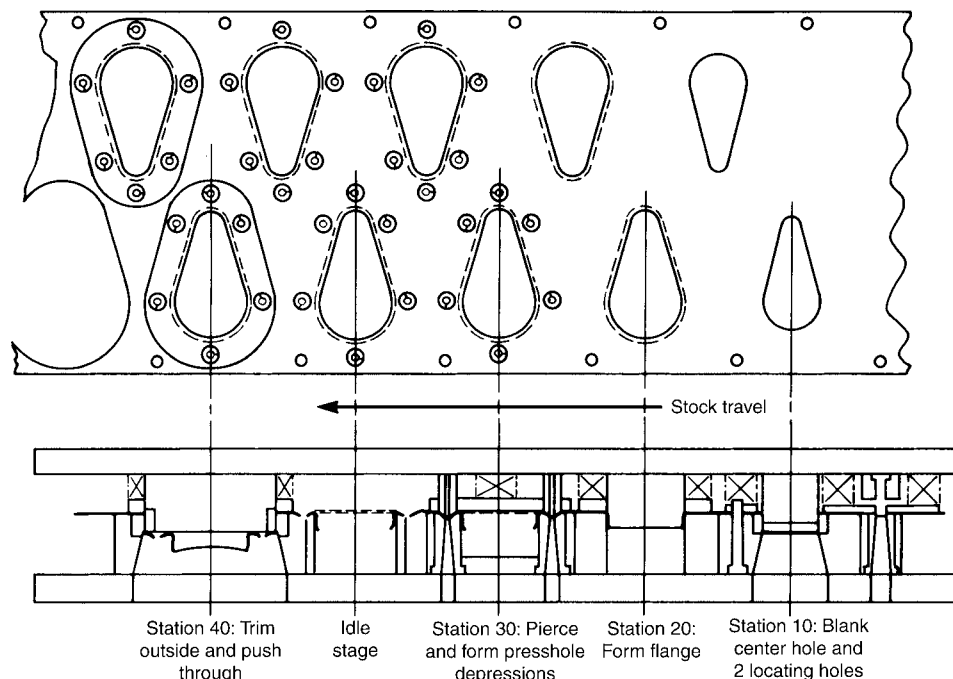

In making the final development, certain principles should be observed to ensure proper die construction. Some of these principles apply generally to all types of dies. Special considerations must be made where the part design involves drawing or forming.

The following principles apply to all types of parts:

- *Pierce piloting holes and notches in the first station of the die.* An important consideration in progressive die work is the proper gaging

**Fig. 1** Strip development for a ring-shaped part. Note locating notch pierced in first station. Flanges formed prior to piercing of nearby holes.

**Fig. 2** Strip development for a ring-shaped part (two at a time). Note idle stage for die strength, layout of strip for material economy.

and location of the part throughout a sequence of operations. Means to facilitate location should be provided in the first operations. These piloting holes or locating points can then be used throughout the remainder of the operations to ensure that a part will be produced according to specifications.

- *Distribute pierced holes over several stations if they are too close to each other or to the edges of the die openings.* While it is recommended that all holes be pierced in the same station, to better maintain tolerances, holes that are too close to each other are apt to cause damage to punches due to crowding of the metal. This can be compensated for in some instances by stepping the punches to permit larger punches to pierce first followed by the smaller punches. However, if the number of holes to be pierced is great, better results may be achieved by spreading out the piercing operations. Holes that would be distorted by subsequent forming operations should be sequenced to follow forming.
- *Design the shape of blanked-out areas as simply as possible.* The lines along which scrap pieces are cut out should be as simple as possible to reduce the problems involved in cutting them out. The simplest designs may

permit the use of standardized commercial punches, thus obtaining maximum advantages with respect to tooling costs.

- *Consider the use of idle stations for strengthening the die and facilitating strip movement.* Although at first glance it may seem that it would be best to perform work in each and every station of a die, there are many cases in which an idle station offers concrete advantages. At best, a progressive die involves cramming of numerous operations into a short space. The various operating tools are set in the main die body in die sections. The existence of numerous die sections tends to weaken the overall die. By the addition of one or two idle stations, the die can be materially strengthened. Movement of the strip, and control of the metal, also can be facilitated by the inclusion of idle stations. There are often severe forces at work in adjoining work stations that tend to break the carrier strip. If an idle station is placed between two such stations, stresses are exerted over a greater length of strip, providing greater protection.
- *Provide for uniform loading of the press slide.* In a progressive die, there are numerous forces at work. Pressures are mostly vertical, but in many cases sideways thrusts are

encountered. These sideways thrusts should be balanced out as much as possible to prevent damage to punches and dies. Special emphasis should be placed on this factor because of the costly nature of the tools. In addition, damaged tools will result in inferior-quality parts. Balance may frequently be achieved through proper sequencing of operations.

- *Provide for efficient scrap disposal.* The use of a progressive die is aimed primarily at increasing the productivity of a stamping operation. Ineffective scrap removal poses a serious threat to the attainment of this objective. In developing die design, space should be allowed for scrap chutes or other means of efficient scrap removal.
- *Provide efficient means of unloading finished parts.* Parts to be drawn present special problems in the design of progressive dies. Proper provisions must be made to supply the metal required to shape the part. Special care must be taken to provide means of moving the part from station to station.

In the development of progressive dies for drawing, the following principles should be observed:

- *Allow adequate provision for lifting the strip from drawing punches.* Where drawing is involved, the strip must be lifted well above the drawing punch or out of the die cavity before it can advance. Because of this, space must be provided in the die to permit incorporation of mechanical lifters.
- *Provide adequate carrier strips and tabs to allow metal movement.* As drawing takes place, the edges of the blanked-out portion of the strip are pulled in. This in turn exerts tensile stresses on the carrier strip. In fact, a center carrier strip may supply a portion of the metal required for the draw. This requires that the carrier strip be of sufficient size and strength to avoid breakage and of proper design to allow metal to flow into the die cavity.
- *Drawing stages should be properly balanced.* In progressive die design, attempts should not be made to draw too deeply in one station in an effort to reduce the number of draws required. Sound judgment must be used in determining the number of draw stations. It is better to spread the drawing operations out

Fig. 3 Basic blank shapes

Fig. 4 Single-row blank layouts (shaded areas represent punches)

Fig. 5 Double-row blank layouts (shaded areas represent punches)

than to work too close to the allowable drawing limits. If excessive draws are attempted, the parts may rupture or tear. The tonnage load on the press may be too great, causing breakdowns. A progressive die with an extra station is less costly than a die of fewer stations that will not produce satisfactory parts.

## General Design Features of Progressive Dies

Progressive dies are used for many small parts where tolerances and specifications are relatively severe. Production requirements of parts produced on these dies are high. Because of these factors, quality of design and structure in progressive dies must be of high caliber.

**Strength.** Progressive dies must be constructed sturdily to withstand sustained high-speed production. This calls for the selection of very strong materials for use in making the die. Areas of greatest stress must be properly built up and reinforced.

The design of progressive dies usually calls for die inserts and retainers and a sectional type of construction. This type of construction is necessary to incorporate the various types of operations that are united in a progressive die. Unless the various die components are properly distributed and strengthened, maintenance costs are apt to be very high.

To facilitate die repair, holes should be supplied in stripper plates and in other areas to facilitate removal of die sections. If such holes are not provided, it may be necessary to dismantle the entire die to remove a single section.

Punch retainers and die-button retainers should be backed up by steel plates to prevent the retainers from penetrating the die material. The die body itself should be made of steel if the demand for die strength is sufficiently high. Where cast iron is used in the die body, special steel wear plates and reinforcements should be added to prevent breakage or excessive wear.

**Guiding.** The precision requirements, plus the rapid cycling involved, require that the mating portions of the progressive die section be carefully guided. Precision guide pins with steel-backed bronze bushings should be used at all four corners of the die to help ensure exact alignment of mating surfaces. Stop blocks should be built into the die to prevent the punch from descending too far. These blocks should be placed where press operators cannot put their hands on them during operation. Guide pins should be long enough so that they are engaged at least 13 mm ( $1/2$  in.) at the beginning of the press stroke.

All progressive die sets should be adequately heeled. Heeling of all die sets is a practical way of maintaining proper alignment of upper and lower shoes. The heels will offset any tendency of side thrusts to disturb die alignment.

In order to ensure that heels do the job for which they are intended, sufficient bearing surface must be engaged. The heels should be engaged a minimum of 13 mm ( $1/2$  in.) at the bottom of the stroke.

Guide pins, stop blocks, and heel blocks must be provided with suitable safety guards to prevent injury to press operators. They should be shielded wherever there is a possibility of someone getting caught in them. Sheet metal is generally used for shielding. Shielding also provides protection of the press and die by keeping out scrap and other materials that could cause difficulty.

**Strippers.** Progressive die sets usually employ stripper plates to free the die tools from

the part being worked on. A stripper prevents distortion of the part and helps to ensure speedy operation. For best operating results, certain factors should be observed in the use of this tool.

The stripper's holes should be carefully designed to allow free movement of punches and other tools through them. Adequate clearances should be provided to prevent binding or excessive wear. Spring strippers should be well regulated with respect to travel. They should be supplied with springs that are sufficiently long to avoid excessive compression. Springs must be strong enough to depress all stock lifters that may be used.

Guiding of strippers is also important. Gibs should be used on two sides of the stripper to provide proper control.

Strippers should be made strong enough, and of a steel that is suitable, for the prevailing working conditions. If parts of a stripper break, they are apt to fall on die surfaces and result in injury to the die.

**The lifters** used to facilitate movement of the strip through the die must also be constructed so as to withstand operating conditions. Breakage of lifters will often result in scored and damaged dies.

**Ejectors.** The full effectiveness of progressive die operations cannot be realized if swift, positive means of ejecting the part from the press are not provided. Presses using these dies are usually automatic in operation and run continuously until stopped by the operator. This rapid cycling provides only a short time for removal of the part.

Mechanical ejectors should be provided for removal of parts. Where there is a possibility of the part falling back into the die, air blasts should be incorporated to make ejection speedier and more positive. Air valves should be checked frequently for timing so that the part cannot fall out of the path of the blast.

## Auxiliary Equipment

The nature of progressive dies demands the choice of proper auxiliary equipment in order to ensure effective operations.

**Coil Feeders.** Most progressive die operations use coil stock. Coil feeders are used to pass the stock into the die. These feeders must possess the proper capacity for holding the required stock and should be designed to administer the proper amount of metal to the press at each cycle. Some coil feeders are merely holders for the stock, with automatic feed rolls being used to move the stock. Others are geared to the press cycle and actually feed in the stock.

**Scrap Handling.** An aspect of some progressive die operations not found in other types of operations is the requirement for handling a carrier strip. This strip issues from the press as finished parts are cut away. Some presses are equipped with devices that roll up this strip as it comes out of the press. In other instances, scrap cutters are mounted at the end of the die to chop

Fig. 6 Triple-row blank layouts (shaded areas represent punches)

Fig. 7 Parts positioned for wide (top) and narrow (bottom) runs

the strip into easily managed lengths. Where the latter method is used, stock boxes or scrap chutes should be used to provide simple means for getting the scrap away from the press.

### Presses Used with Progressive Dies

In selecting presses for progressive die work, certain considerations are involved. Some of these considerations include the volume requirements of the part, the accuracy required, the size of the part, pressure requirements, and the relative difficulty of producing the part. Many types of presses are used for this kind of work. The choice will depend on how well the press meets the needs of a given situation plus the inescapable factor of press availability.

**Open-Back Inclinable Presses.** Numerous progressive operations are performed in open-

back inclinable presses. The inclined feature of this press provides an often satisfactory solution to the problem of removing parts because the parts tend to fall easily out of the back of the press. Where a multiple die is used to make two or more parts at a time, a choice must be made as to whether to let the parts running at the uppermost level of the die drop out of the rear or whether to use an air blast to blow them out of the front of the press.

Tie rods usually are used across the gaps of these presses where exceptional accuracy is required. This is done to prevent deflection of the press under load.

Because of pressure limitations, gap-frame presses are usually used on the smaller types of progressively shaped parts.

**Four-Column Presses.** For progressive work demanding high pressure and exceptional accuracy, straight-side four-column presses are

frequently used. This type of press is generally superior in tonnage potential to gap-frame presses. In addition, the four columns absorb sideways thrusts to ensure better alignment of punch and die.

For both gap-frame and straight-side presses, the press bed must be sufficiently wide to provide room for the progressive die used.

**Automatic underdrive presses** are designed specifically for use with progressive dies. They have wide beds and provisions for easy application of automatic loading and unloading.

### ACKNOWLEDGMENT

This article was adapted from the chapter "Progressive Dies" by O.D. Lascoe in *Handbook of Fabrication Processes*, ASM International, 1988.

# Prediction and Direct Measurements of Die Wear in Stamping Processes

Huimin Liu, Materials Surface Engineering and Testing, Ford Motor Company\*

IN AN EFFORT to improve the fuel economy of automotive vehicles, various approaches have evolved in the past decades. Among them, the use of high-strength steels (HSS) for automotive body-in-white (BIW) parts has proven to be an effective means of reducing vehicle weight for similar or superior vehicle performance to thicker-gage mild steel parts. More recently, advanced high-strength steels (AHSS) have attracted increasing attention for emerging applications in vehicle body structures.

In stamping operations of sheet metals for automotive BIW parts, wear of draw dies and draw beads occurs as a result of high, localized contact pressure and friction between the sheet metals and die surfaces, among others. Die wear may take place in various forms, such as changes in radii, peeling off or wearing out of surface coatings, scratches, galling, and/or pitting of the die surfaces. In the past, due to lack of a theoretical formula for prediction of die wear rate, die surface treatments during stamping productions were conducted only when galling or scratching of both or either of the die surfaces and/or part surfaces was observed, compromising the quality and consistency of the stamped parts. In addition to the structural robustness and durability of stamping dies, die wear may also pose a significant challenge to stamping productions of AHSS. The extremely high contact pressure and heat generated due to deformation of high-strength sheet steels may accelerate die wear, which may lead to instability in part dimensions and degradation of part surface quality and part safety. Thus, automotive original equipment manufacturers (OEMs) have been concerned about stamping AHSS and ultra-high-strength steels (UHSS).

Therefore, there is a critical need for understanding the wear mechanisms and quantifying the rate of die wear for various die surface coatings, bead geometries, lubricants, and different sheet metals, particularly HSS and AHSS.

This article describes laboratory techniques for direct measurement and quantification of

die wear in verifying a proprietary die-wear predictor methodology developed by the author. The method is based on a theoretical formula (referred to as a die-wear predictor) that can be used to predict the rate of die wear and the life of a die surface coating, applicable to both mild steel and HSS stampings (Ref 1). As background, the die-wear predictor is used to:

- Correlate the rate of die wear or the life of a die surface coating to stamping process parameters, die surface properties, die/bead geometries, sheet metal properties, and lubrication, applicable to both mild steel and HSS stampings
- Enable the prediction of wear depth of draw die radii or beads at a given number of drawings (hits) so that an accurate maintenance schedule can be established that prevents part dimension instability, surface defects, and safety deterioration from occurring
- Provide guidelines for selecting the best combination of a die surface coating and a stamping lubricant for a given part, program volume, and die design
- Develop or optimize new die design, buy-off, surface treatment, and coatings by tool and die makers and surface coaters
- Establish maintenance schedules at stamping plants

Figure 1 summarizes the functions of the Ford die-wear predictor. A personal computer-based software version has also been developed by Ford Motor Company.

## Wear Mechanisms

**Primary Wear Mechanisms.** In solid-surface interactions, there are four primary wear mechanisms that cause loss of mass from surfaces: adhesive wear, abrasive wear, erosive wear, and fatigue wear.

*Adhesive wear* is the most common form of wear. When two solid surfaces slide over each other, asperities on one surface come into contact with asperities on the other surface. Particles/fragments may be pulled off of one surface to adhere to the other. The particles may come off the surface and be transferred back to the original surface or form loose particles.

*Abrasive Wear.* When a rough, hard surface (or a soft surface containing hard grains) slides over a softer surface, the hard surface makes a series of scratches in the softer surface. The material from the scratches is displaced in the form of loose particles.

*Erosive Wear.* Chemical attack by aggressive ingredients in a wet lubricant to a smooth surface causes formation of a corrosive film or patches on the surface. The corrosive product can be sheared away during sliding of another surface over it, causing continuation of the corrosive attack.

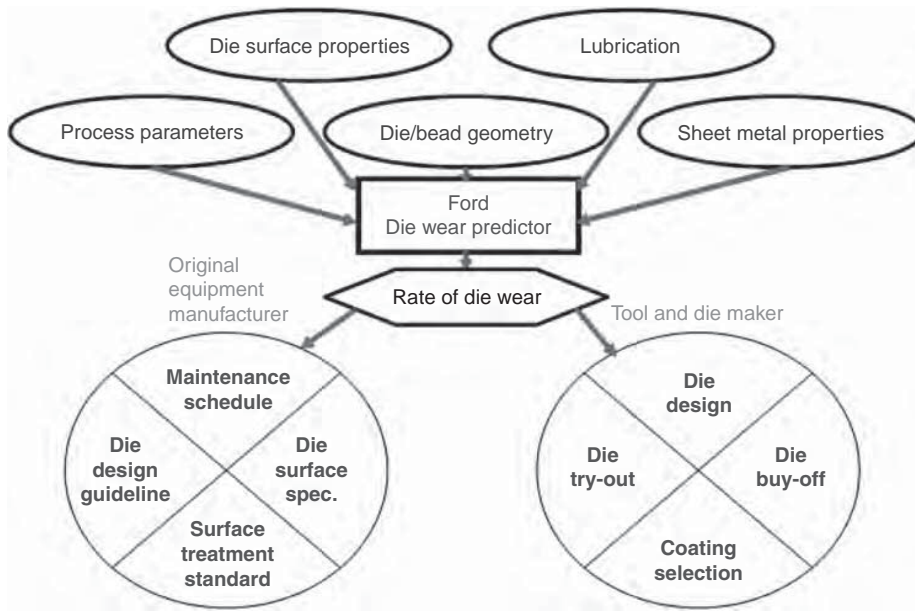

*Fatigue wear* may occur in repeated sliding over a surface. The cyclic loading and unloading on a surface may induce the formation of surface cracks. Delamination may take place subsequently, causing breakoff of large fragments from the surface and leaving large pits in the surface.

**Operating-Wear Mechanisms in Stamping Productions.** In stamping operations, tool/die surfaces are normally harder and significantly smoother than sheet metal surfaces. The wear of tool/die surfaces may occur in mixed modes of adhesive, erosive, and fatigue wear.

Sheet metal surface galling may occur during stick-slide, that is, metal draw-in, causing loose particle transfer to the tool/die surfaces. When the sheet metal slides over draw beads, high contact pressures at metal-bead contact areas cause high temperatures due to metal deformation, surface friction, and very high shear stresses at the local spots, which may lead to delamination of small surface patches. The bead surface asperities may be sheared off

## 2 / Prediction and Direct Measurements of Die Wear in Stamping Processes

**Fig. 1** Applications of Ford Motor Company die-wear predictor

during thousands of cyclic sliding under the action of high compression and friction forces.

Stamping lubricants, particularly blankwash, cause electrochemical reactions between the wet lubes and the tool/die surfaces, leading to local surface damages that are accelerated by the high contact pressures and temperatures at the contact areas.

In current HSS stamping productions, the emphasis is placed on die surface treatment to extend die life. Due to the excellent surface coating conditions, additional lubrication and/or cooling is seldom necessary. Therefore, adhesive wear and fatigue wear mechanisms are the main focus to assess the effects of various material/process/design parameters on draw bead wear. The effects of lubricants on surface temperatures and die wear in AHSS stamping is a subject of additional consideration.

### Direct Measurements of Die Wear—Lab Techniques

The die-wear predictor was verified and validated by long-term plant monitoring data and extensive wear tests at Ford Motor Company's facilities. In the labs of Ford Motor Company, a series of friction tests and extensive wear tests were completed on mild steels and HSS with various electrogalvanized (EG) or hot dip galvanized (HD-GI) or hot-dip galvanealed (HD-GA) coatings and different die materials (S0050A, D2, M2), either bare, treated (ionitrized), or coated with various die surface coatings (chromium, CrN, CrC, WC, MoS<sub>2</sub>, TD VC) during a period from 2003 to early 2005.

Several novel techniques were developed by the author to directly measure die wear and to

quantify die wear as a function of the number of drawings. Detailed analyses of wear mechanisms, microstructure, and micromorphology evolutions were conducted using an advanced three-dimensional (3-D) laser technology, optical microscope, and scanning electron microscope (SEM) coupled with other advanced analytical techniques and measurement instruments in the Ford labs. The lab studies also include characterization of the surface conditions of both the sheet metal and draw dies/beads over the number of drawings, measurements of the temperatures and roughness of both the draw beads and sheet metal over the number of drawings, quantification of the material transfer and die buildup with drawing, measurements of the drawing/binder forces and die wear as a function of drawing, and measurements of the initial and final microhardness of the draw bead surfaces.

Details of the direct measurement techniques are described in this section. Indirect nondestructive measurement techniques for plant monitoring are presented with plant findings in a companion Handbook Online article, "Indirect Nondestructive Measurements of Die Wear in Stamping Productions." The novel techniques developed by Ford Motor Company for direct measurements of die wear involve the following procedures:

- Drawing of sheet metal samples using a laboratory wear tester that simulates metal flow (or metal draw-in) through draw beads or over radii or steps in stamping operations
- Measurement of surface roughness of sheet metal samples (Fig. 2) and draw beads (Fig. 3) using two- and three-dimensional surface profilometers

- Characterization of surface conditions of sheet metal samples and draw dies/beads using stereomicroscopes and SEM
- Measurement of drawing and bead forces using a laboratory wear tester
- Quantification of material transfer and buildup of coating debris on draw beads using an analytical balance
- Measurement of surface temperatures of sheet metal samples and draw beads using a digital thermometer
- Measurement of mass loss of draw beads due to wear using an analytical balance
- Direct measurement of wear of draw beads using a 3-D laser scanner (Fig. 4)
- Measurement of initial and final microhardness of draw bead surfaces using a microhardness tester

Figure 2 illustrates the sheet metal samples after drawing in the wear tests, where the sheet metal is HD-GA dual-phase (DP) 500 (DP500) without any stamping lubricant. Figure 3 depicts the dies and draw beads used in the wear tests. Figure 4 shows the 3-D laser scanner used for direct measurements of draw bead wear in the wear tests.

### Evolution of Surface Conditions of Sheet Metal, Draw Dies, and Beads during Wear Testing

Figure 5 shows the change in surface conditions of the sheet metal with drawing. For less than 15,000 drawings, no surface galling is observable with the unaided eye. At 15,000 drawings, the springback of the sheet metal is less pronounced than at 5000 or 1000 drawings, suggesting higher interfacial friction at 15,000 drawings. Surface galling can be observed at 25,000 drawings, where springback is even less pronounced than at 15,000 drawings, suggesting an even higher interfacial friction at 25,000 than at 15,000 drawings. At 35,000 drawings, the surface galling is the most severe, and the sheet metal draw-in is less than at 25,000 drawings. This reveals that surface roughening is most severe at 35,000 drawings, where the resultant very high interfacial friction restrains the sheet metal draw-in. At 40,000 drawings, the surface galling condition is similar to that at 25,000 drawings; however, the metal draw-in is less than at 25,000 drawings. At ~49,000 drawings, the surface galling is severe, and several loose particles can be seen pressed into the sheet metal, forming dents. In addition, the springback condition is similar to that at 35,000 drawings, although the sheet metal draw-in is less. It appears that beyond 25,000 drawings, the surface roughening and springback conditions change in a cyclic or roller-coaster pattern with drawing, while metal draw-in becomes less and less with continued drawing. Dimensional instability in the drawn sheet metal also follows the roller-coaster pattern beyond 25,000 drawings.

Figures 6 and 7 show the surface condition changes in lower and upper draw dies and draw beads with drawing. Clearly, fine particles of the surface coating on the sheet metal are shaved off and accumulate on the beads and dies while

**Fig. 2** Sheet metal (DP500, HD-GA) samples after drawing-in wear tests

(a)

(b)

**Fig. 3** Dies and draw beads used in wear tests. (a) Lower. (b) Upper

**Fig. 4** Three-dimensional laser scanner for direct measurement of die wear

the drawing proceeds. With increased drawing, the fine powders become larger and larger flakes, while the buildup increases. The heaviest buildup is observable at 35,000 drawings. Beyond that, the buildup appears less but increases again with further drawing beyond 40,000 drawings.

On the upper bead, the buildup is also heaviest at 35,000 drawings, where fine powders and flakes are seen even on the upper die block surface, suggesting a burst of coating materials peeling off from both the sheet metal and the draw bead surfaces at 35,000 drawings. At 40,000 drawings, the buildup is much less and then increases with further drawing.

To understand the behavior of surface conditions with drawing, quantitative measurements and surface analyses are conducted throughout the wear tests, including surface roughness, surface morphology and microstructure, material transfer and buildup of coating debris, interfacial friction, surface temperatures, and wear rate, as discussed subsequently.

**Evolution of Surface Roughness of Sheet Metal and Draw Beads.** Figure 8 depicts the changes in the surface roughness of sheet metal and draw beads over the number of drawings, where the roughness data are normalized by the initial draw bead roughness prior to the first drawing, both in micrometers ( $\mu\text{m}$ ).

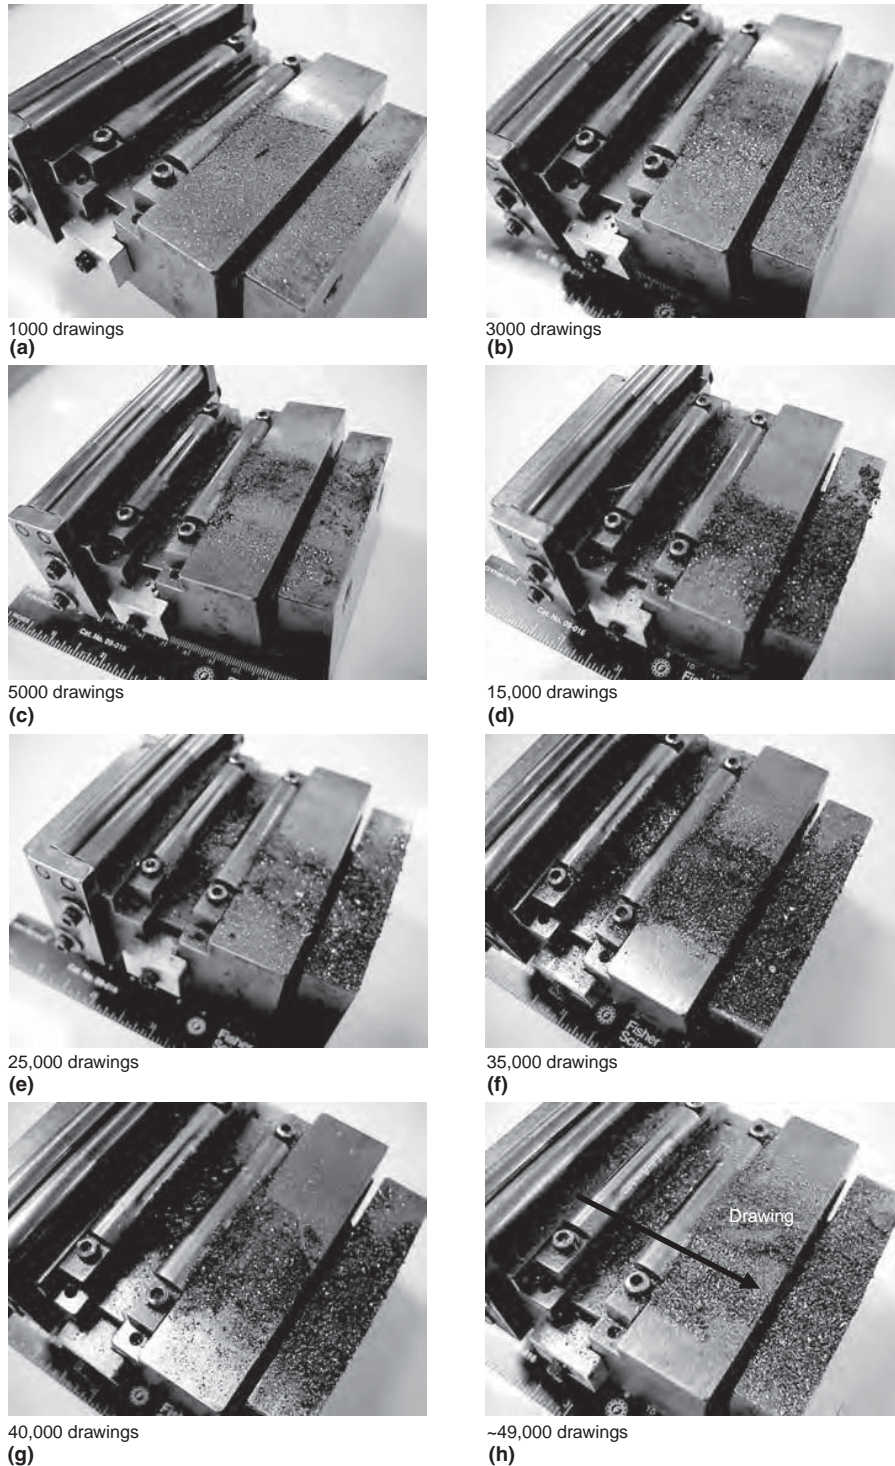

The measured roughness data show that:

- The surface roughness height ( $R_a$ ) of the sheet metal increases dramatically (virtually exponentially) in the early stage and then changes in a roller-coaster fashion with further drawing beyond approximately 15,000 drawings. This pattern corresponds closely to the change pattern of surface galling, springback, and dimensional instability of the drawn sheet metal, as discussed previously, and therefore explains why severe surface galling is observable beyond approximately 15,000 drawings.
- The surface roughness height ( $R_a$ ) of the draw beads also increases significantly in the early stage. From 15,000 to 35,000 drawings, the surface roughness of the draw beads increases dramatically and reaches its maxima at 35,000 drawings, beyond which

**Fig. 5** Change in surface conditions of sheet metal with drawing. (a) From top to bottom: 0 (initial condition), 1000, 5000, 15,000, 25,000, 35,000, 40,000, and ~49,000 drawings. (b) Close-up views of sheet metal surface conditions at the beginning and end of wear tests

**Fig. 6** Surface condition change and buildup on lower draw die and beads with drawing

the changes in surface roughness follow the roller-coaster pattern.

- In general, the surface roughening of the lower bead is most severe at the exit side, followed by the lower bead at the entry side, and then the upper bead at the exit side. The

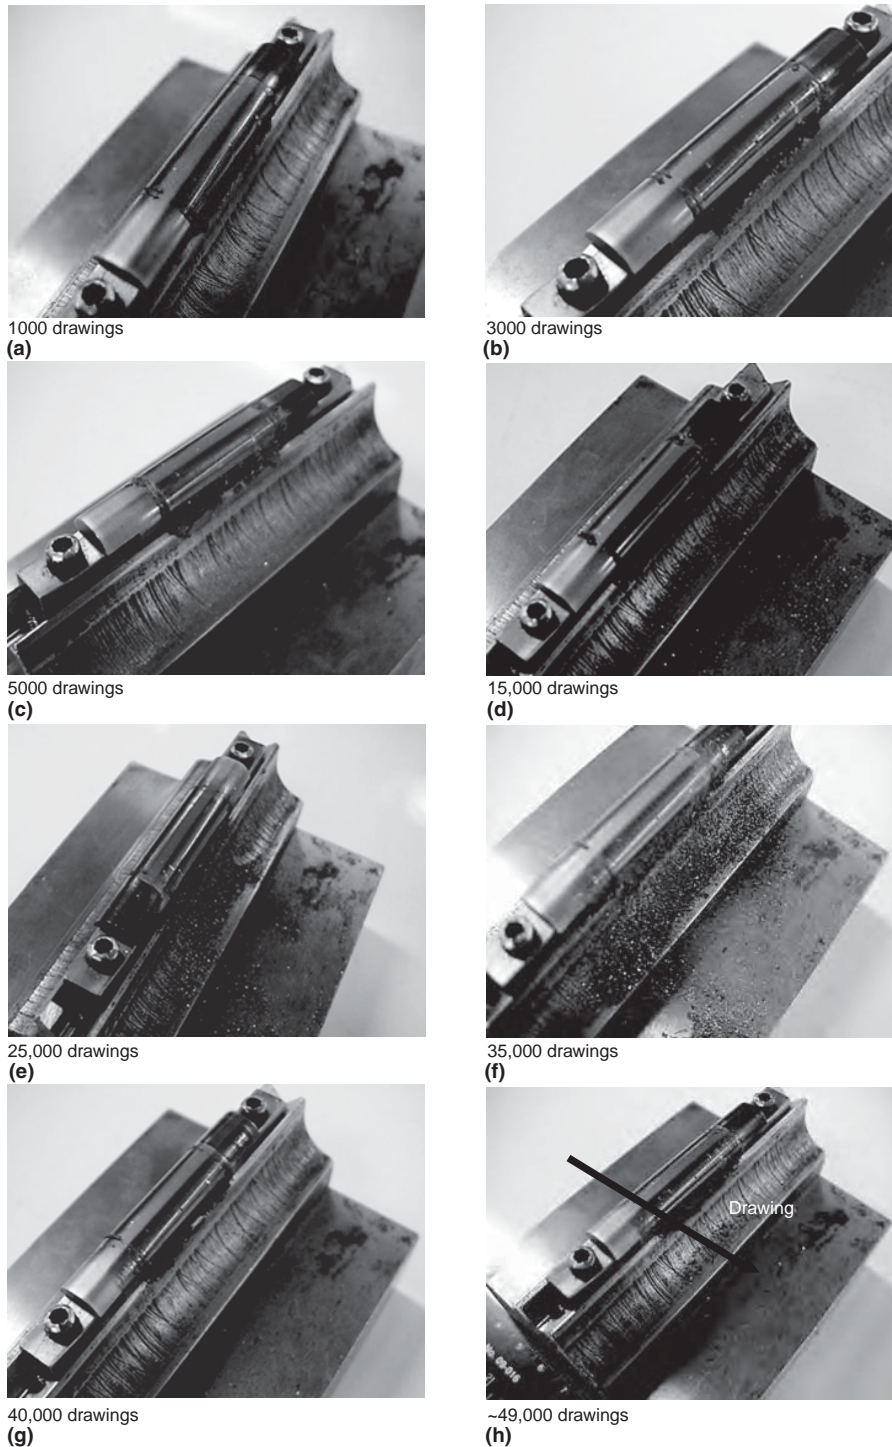

surface roughening of all beads follows the same roller-coaster pattern, suggesting that the same wear mechanism governs the roughening phenomenon, and the difference in the roughening extents is due to the different contact pressures on the various bead

contact areas. This finding reveals that contact pressure should be highest at the contact area on the lower bead exit side, followed by the lower bead entry side, and then the upper bead exit side. The contact pressure on the upper bead entry side should be lowest, leading to the least roughening. These results explain why the surface galling of the sheet metal is more severe on the bottom side, which is in contact with the lower bead, than the top side, which is in contact with the upper bead. It should be noted, however, that the location where the maximum contact pressure occurs may change with bead geometry, configuration and conformity of the sheet metal to the draw beads, and so on. Caution must be exercised when extending the findings of the present study beyond the conditions under which they were derived.

- While the bead surfaces become roughened with increased drawing, at  $\sim 15,000$  drawings the bead surfaces at the contact areas become as rough as the sheet metal (see the intersection of the sheet metal and bead roughness data). Beyond 15,000 drawings, the contact areas on the bead surfaces become rougher than the sheet metal, and the roughening accelerates dramatically with further drawing, again explaining the reason why severe surface galling of the sheet metal is observable beyond 15,000 drawings. At 40,000 drawings, there is another intersection between the sheet metal roughness and upper bead roughness, suggesting severe cold weld occurred on the upper bead at the contact areas. These variations in roughness with increased drawing influence the friction behavior at the metal-bead interface and are discussed in more detail as follows.

Since more severe surface galling of the sheet metal is seen at the bottom side, which is in contact with the lower bead surfaces, the lower bead surface roughness in the exit contact area should be used to determine when a die surface treatment is necessary. In addition, bead surface roughening accelerates dramatically beyond the point where the bead surface becomes rougher than the sheet metal surface. Accordingly, when the lower bead surface in the exit contact area becomes as rough as the sheet metal surface, caution should be exercised; further, when it becomes more than three times rougher than the sheet metal surface, a die surface treatment should be rendered to avoid excess surface galling and dimensional instability of the stamped parts.

**Evolution of Surface Morphology and Microstructure of Draw Beads.** To understand the roller-coaster change pattern of surface roughness with increased drawing, the draw beads and the bead surfaces at the contact areas, referred to hereafter as wear bands, are examined using a high-magnification stereomicroscope. Figures 9 to 11 show the micrographs of wear bands on the lower bead exit side, lower bead entry side, and upper bead exit side, respectively.

**Fig. 7** Surface condition change and buildup on upper draw die and bead with drawing

While all three sets of micrographs show continuous surface roughening at the wear bands from 15,000 to 35,000 drawings, some cold weld phenomena can be seen at 40,000 drawings as a result of transfer of loose particles from the sheet metal to the bead surfaces, leading to the reduced roughness height at

40,000 drawings, as discussed previously. With further drawing beyond 40,000 drawings, the material transfer between the sheet metal and bead surfaces continues, while the bead surfaces enter into a roughening cycle. At ~49,000 drawings, the bead surfaces at the wear bands become rougher than at 40,000

drawings as a result of the continued material transfer. This roller-coaster pattern should repeat with increased drawing. Note that the roughening of the lower bead at the exit contact area is much more severe than that of the upper bead, suggesting the significant effect of contact pressure on accelerated wear. Additionally, under the action of gravity, a certain amount of loose particles may also drop from the sheet metal to the lower beads when the die is opened in each draw-open cycle, which may have contributed to the much more severe roughening of the lower bead at the exit contact area. For the same reason, fewer loose particles are observable on the upper bead surfaces at the contact areas.

The surface morphology, microstructure, and chemistry of draw beads coated with CrN are examined using an SEM (Fig. 12) following ultrasonic cleaning of the beads. The wear morphology (Fig. 12d) and surface chemistry are similar at all wear bands on lower and upper beads. For example, for the CrN-coated beads after ~49,000 drawings, the smooth regions outside the wear bands on all beads show a uniform chromium coverage in the SEM map (Fig. 12a), whereas the rough areas (wear bands) show obvious disruptions in the coating. A large amount of iron (Fig. 12b) is found in these disruptions, suggesting that the CrN coating is worn off from the disrupted regions, exposing the steel substrate (draw bead material). A few iron particles may be transferred from the sheet metal samples during adhesive wear. In addition, there are several small discrete domains of zinc (Fig. 12c) in and around the disrupted regions. The zinc particles are apparently from the sheet metal samples during adhesive wear. The majority of the zinc particles transferred from the sheet metal samples to the beads during adhesive wear were cleaned off from the wear bands, enabling examination of the morphology and microstructure of the wear bands on the draw beads.

A detailed adhesive wear mechanism can be derived from these SEM analyses. It appears that during the early stage of wear, the bead surfaces are roughened at the contact areas with the sheet metal. The loose zinc particles from the softer sheet metal surfaces are sheared off by the asperities on the harder bead surfaces. Some of the zinc particles are transferred to the bead surfaces on the contact areas, where they accumulate and lower the roughness of the bead surfaces. When the particles are accumulated to the extent that they change the local contact pressures at certain regions, the local contact pressures may be high enough to shear off microparticles from the bead surface asperities, causing collapse of the accumulated zinc particles and peeling off, along with the bead surface particles. This leads to roughening of the bead surfaces at the contact areas. These loose particles may transfer to the sheet metal surfaces, roughening the sheet metal surfaces. The thousands of repeats of this particle-transfer process cause the grooves to become deeper and

**Fig. 8** Evolution of surface roughness of sheet metal and draw beads, normalized by initial surface roughness of draw beads

wider on both the bead and sheet metal surfaces, that is, wear. This mechanism also explains the roller-coaster behavior of surface roughness with increased drawing, as discussed previously.

**Evolution of Material Transfer and Buildup of Coating Debris on Draw Beads.** Figure 13 shows the material buildup on/in draw beads with increased drawing, where the buildup in grams per square meter of drawn sheet metal surface area per sample drawn is normalized by the HD-GA coating weight on the sheet metal surface in grams per square meter ( $\text{g}/\text{m}^2$ ).

It should be noted that the buildup material was collected from the beads using a small stick with a cottonball tip, and therefore, the weight for the buildup material may be underestimated, particularly for the upper bead, where some buildup material was caught in between the bead insert and die block. In addition, some buildup material may drop from the upper bead onto the lower beads during continuous drawing, and a certain amount of buildup material may be lost during handling, introducing additional uncertainty to the measured buildup weight data. Nevertheless, the tendency shown in Fig. 13 appears consistent, in general, with the bead surface roughness evolution discussed previously.

From Fig. 13, it can be seen that the material buildup on/in the lower beads is much more than that on the upper bead. For example, at 35,000 drawings, each sheet metal sample loses  $\sim 0.2\%$  of its coating weight onto the lower beads, whereas less than only  $0.02\%$  of its coating weight is lost onto the upper bead. Nevertheless, the increased buildup with increased drawing on both the lower and upper beads

shows the similar roller-coaster pattern to the previously discussed bead roughness evolution. For example, at 35,000 drawings, the buildup on/in the lower beads reaches a local maximum where the bead surface roughness attains a peak value as well. From 35,000 to 40,000 drawings, the buildup on/in the lower beads decreases and then increases from 40,000 to  $\sim 49,000$  drawings. This trend corresponds very closely to the bead surface roughness change over the same range of drawings. These similar patterns suggest that the rougher the bead surfaces, the more material buildup on the beads. Additionally, the sheet metal surface roughness also influences the material transfer and the buildup of coating debris on the beads during the early stage of wear when the bead surface roughness is less than that of the sheet metal surface. When the bead surfaces become rougher than the sheet metal surface, the change in material transfer and buildup of coating debris over drawing is predominantly governed by the change in bead surface roughness.

**Evolution of Friction Behavior at Metal-Die Interface.** Figure 14 shows the change in drawing force with increased drawing, where drawing force is normalized by binder force, both in kilonewtons (kN).

Unfortunately, force data could not be acquired over the 10,000 to 34,000 drawings range. However, the general trend that can be derived from the acquired data (Fig. 14) is obvious; that is, the normalized drawing force initially rises drastically (from 0 to 10,000 drawings), and then its increase over drawing becomes more gradual, with a large amount of

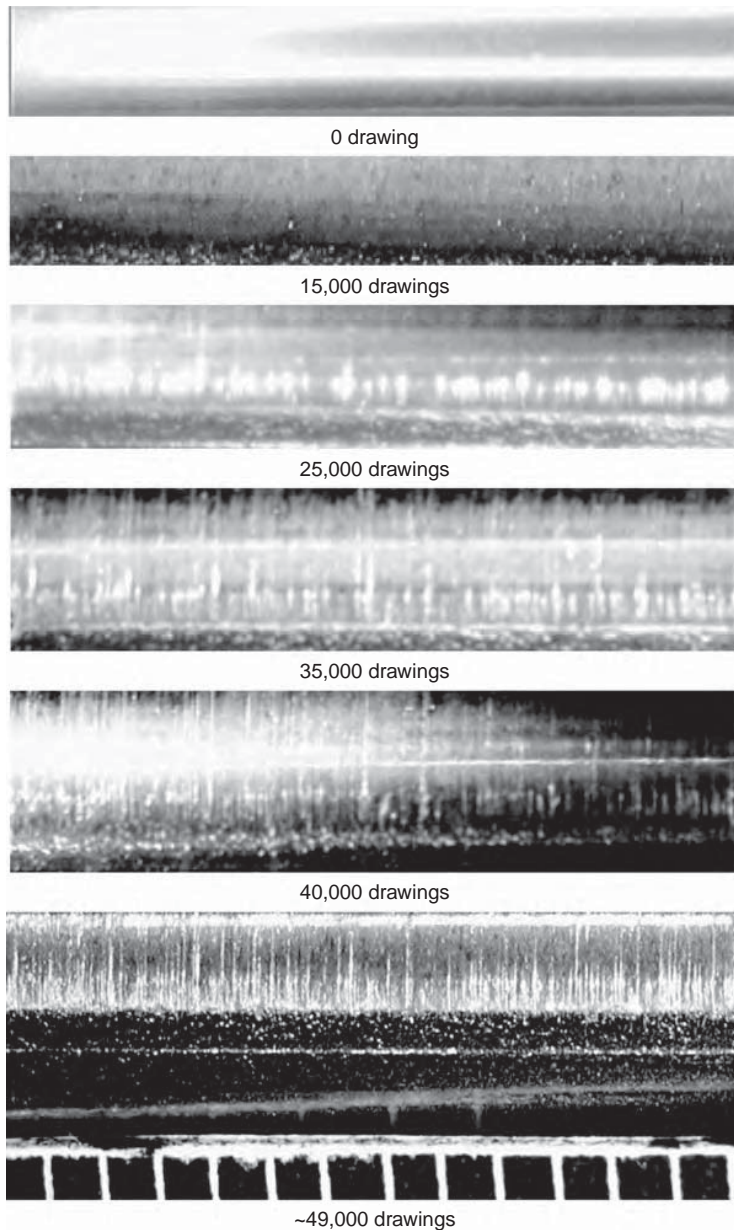

scatters. The scattered data suggest significant variations or instabilities due to material transfer during adhesive wear.

The effects of surface roughness (Fig. 8) and material buildup (Fig. 13) on interfacial friction (Fig. 14) do not appear linear. Surface roughness seems to dictate interfacial friction behavior before the draw bead surface becomes rougher than the sheet metal. Beyond this point, the effect of material buildup on the draw beads becomes more and more important. For example, during the initial stage, the surface roughness of the sheet metal increases rapidly with drawing and then becomes more gradual, in a roller-coaster fashion but at much smaller amplitude than that of the draw beads. Correspondingly, the interfacial friction increases sharply with drawing in the early stage and then much slower with more oscillations. With the drastic increase in bead surface roughness at 35,000 drawings, it would be expected that interfacial friction would attain its local maximum as well. However, interfacial friction peaks at  $\sim 40,000$  drawings, where both bead surface roughness and material buildup on the lower bead decrease to their local minima. This suggests that material buildup on the draw beads may have functioned as a solid lubricant at the interface, so that where material buildup on the lower bead peaks (e.g., at 35,000 drawings), interfacial friction is lower, while where material buildup on the lower bead drops (e.g., at 40,000 drawings), interfacial friction is higher in spite of the lower bead surface roughness at 40,000 drawings as compared to that at 35,000 drawings.

**Evolution of Surface Temperatures of Sheet Metal and Draw Beads.** Figure 15 shows the evolution of the surface temperatures of draw beads and sheet metal during drawing, where the temperatures of the beads are the average of the entry- and exit-side temperatures in the center of each contact area (wear band), and all temperatures are normalized by the actual room temperature in degrees Fahrenheit ( $^{\circ}\text{F}$ ).

The measured temperature data reveal that:

- The surface temperature of the sheet metal is much higher than the draw bead temperatures over the majority of the drawing process.
- The surface temperatures of the draw beads increase virtually linearly with the number of drawings.
- The surface temperature of the sheet metal increases with the number of drawings virtually exponentially in the early stage, and then the increase becomes more gradual, with large scatters in a roller-coaster fashion with further drawing beyond approximately 15,000 drawings, suggesting the onset of instability induced by typical adhesive wear.
- The temperatures of the lower and upper beads are lower at the entry side than the exit side. The higher temperatures at the exit side are because (1) the contact pressure is higher at the exit side, and bead surface roughening is more severe at the exit side, so that more friction-induced heat is

**Fig. 9** Evolution of surface roughness of draw beads—lower bead exit side (scale in mm)

generated at the exit side; and (2) the sheet metal experiences further bent-unbent deformation and work hardening, which generate more heat that is transferred to the draw beads at the exit side.

- The difference between the entry-exit temperatures of the lower beads is larger than that of the upper bead because the upper bead is one piece that dissipates heat through conduction, so that the temperature gradient from the entry to the exit side is lower, whereas the lower beads are two inserts and separated farther apart than the entry-exit distance of the one-piece upper bead.

- On average, the lower bead exit temperature is higher than the upper bead exit temperature, although the data are somewhat scattered, suggesting that the temperature is influenced by both friction and deformation of the sheet metal.

The rise of the temperatures of the draw beads and the sheet metal with increased number of drawings may be attributed to two factors: metal-deformation-induced heat and friction-induced heat. The heat generated during deformation of the sheet metal increases the temperature of the metal, but only a portion

of this heat is transferred across the metal-bead interface to the draw beads. If the friction-induced heat at the metal-bead interface would be equally dissipated into the sheet metal and draw beads, the much higher surface temperature of the sheet metal suggests that (1) the metal-deformation-generated heat may be more pronounced than the friction-induced heat; and/or (2) only a small portion of the metal-deformation-generated heat is transferred from the sheet metal to the draw beads via convection and due to the lower thermal conductivity of the surface coating on the draw beads compared to that of the sheet metal or its coating; and/or (3) the larger volume of the draw beads, compared to that of a sheet metal sample, functions as a heat sink; that is, more heat is conducted into the volume from the surface, leading to the lower surface temperature of the beads than that of the sheet metal.

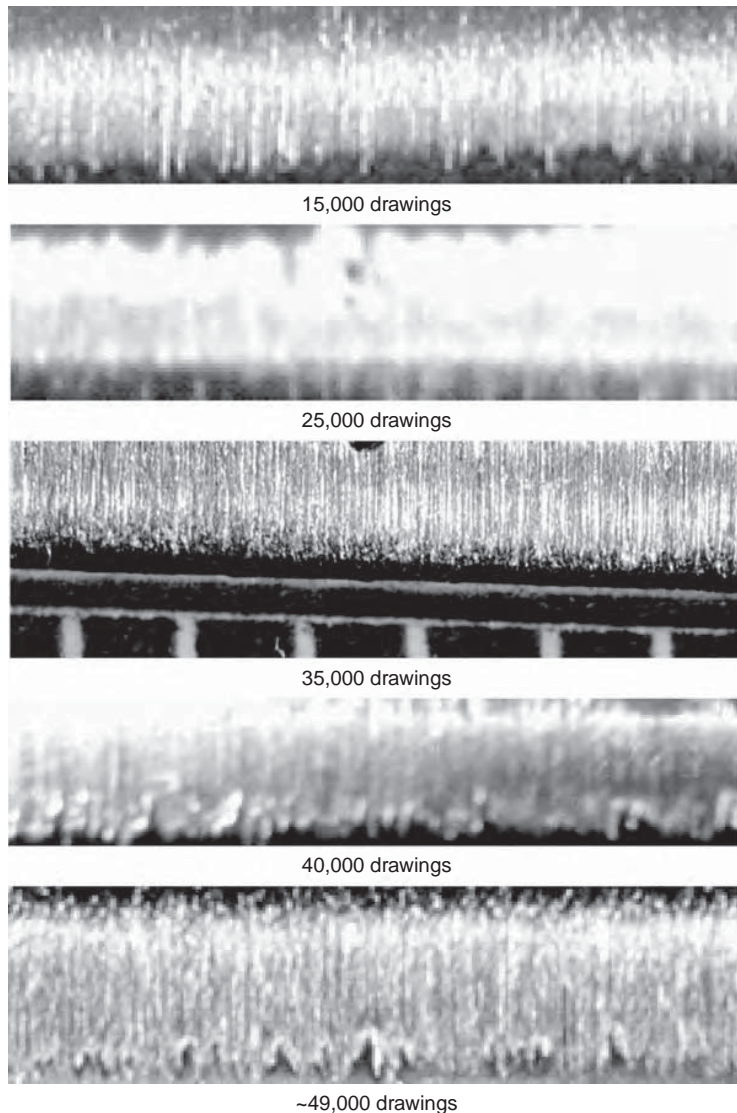

Since the metal-deformation-induced heat is virtually constant from one drawing to the next, assuming that the sheet metal sample size and thermophysical and mechanical properties are constant from one sample to the next, the pattern of increase in the sheet metal surface temperature should correspond to the pattern of increase in the friction-induced heat over the number of drawings. Indeed, comparing the patterns of increases in the sheet metal surface temperature (Fig. 15) to those in the interfacial friction (Fig. 14) and the sheet metal surface roughening (Fig. 8), the tendency is virtually identical. That is, the sheet metal surface roughness, the resultant interfacial friction, as well as the resultant friction-induced heat increase exponentially in the initial stage, and then the increases slow down with further drawings beyond approximately 15,000 drawings. At the same time, the scatters or instabilities in these three sets of data become more pronounced with further drawings and progress in more or less a roller-coaster fashion. This pattern also corresponds closely to the change pattern of surface galling, springback, and dimensional instability of drawn sheet metal, as discussed previously, suggesting the significant effect of metal surface roughening on friction-induced heat generation and the resultant rise of sheet metal surface temperature.

#### Mass Loss and Wear Rate of Draw Beads.

Figure 16 shows the mass loss of the lower draw bead at the exit side with increased drawing, where the mass loss per unit surface area on the wear band of the lower draw bead is normalized by the surface coating weight per unit surface area on the draw bead, both in grams per square meter ( $\text{g}/\text{m}^2$ ).

It can be seen from Fig. 16 that wear is rather severe during the initial stage, where it increases virtually exponentially from 0 to 15,000 drawings. Beyond 15,000 drawings, the wear also follows a roller-coaster fashion as a result of material transfer between the draw bead surfaces and the sheet metal surfaces. When loose particles are transferred from the sheet metal surfaces to the draw bead surfaces,

**Fig. 10** Evolution of surface roughness of draw beads—lower bead entry side (scale in mm)

the mass loss of the draw bead surfaces decreases, for example, at 25,000 and 40,000 drawings. In contrast, when the draw bead surfaces become roughened with continuous drawing, loose particles transfer back to the sheet metal surfaces, which are then shaved off and built up on/in the draw beads, causing an increase in mass loss of the draw bead surfaces after removal of the loose buildup, for example, at 35,000 and ~49,000 drawings. This change pattern of wear corresponds very well to the change pattern of material transfer and buildup on/in the draw beads discussed previously. Under the conditions in this series of studies, it appears that the relatively hard and rough surface coating (HD-GA) on the HSS sheet metal (DP500) caused ~50% mass loss of the surface coating on the wear band of the lower draw bead at the exit side after 15,000 drawings. On average, ~49,000 drawings remove ~98%

of the surface coating on the wear band of the lower draw bead at the exit side.

Based on these data, it can be predicted that, when used as draw bead materials, a surface coating such as CrN on a cast steel such as S0050A could withstand at least 50,000 drawings of an HSS sheet metal such as DP500 with a relatively rough and hard coating such as HD-GA. When used at die or punch radii, CrN-coated S0050A could withstand at least 200,000 drawings of DP500 with a HD-GA coating (one-time bent-unbent as compared to four-times bent-unbent over a draw bead). The maximum number of drawings could be much higher when a lubricant is used and/or a softer and smoother coating, such as HD-GI, is applied on the sheet metal. Therefore, a die surface coating such as CrN appears to be an adequate option for die surface treatments of medium-volume HSS parts that will require only an

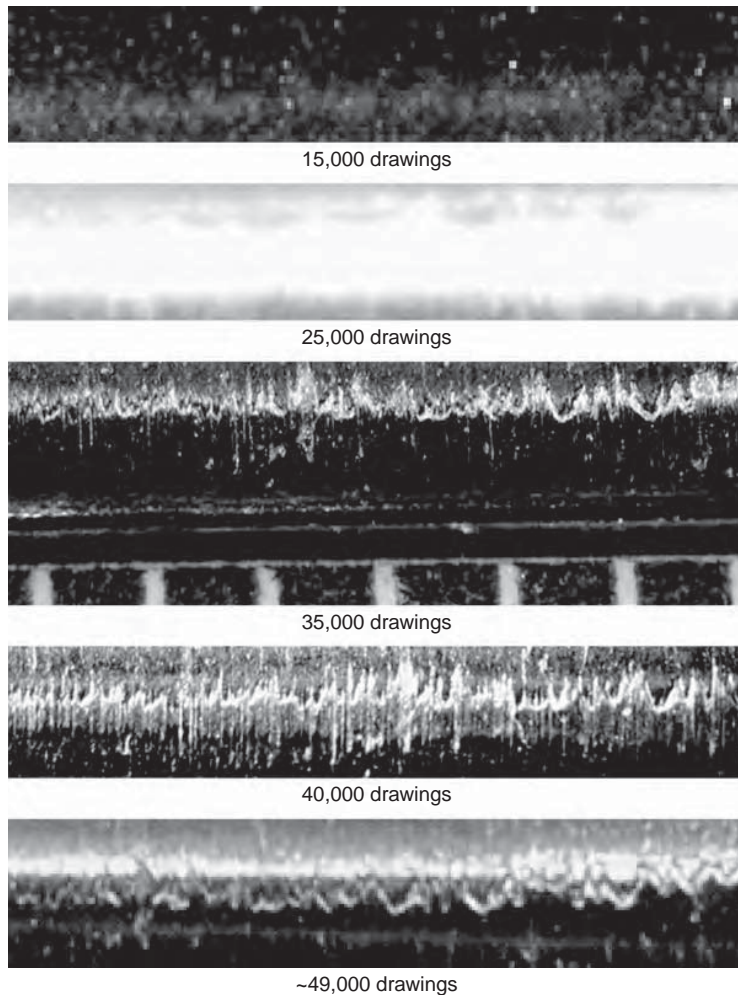

annual resurfacing during normal preventive maintenance.

Figure 17 shows the measured and predicted wear depths of the lower draw bead at the exit side with increased drawing, where the wear depths on the wear band of the lower draw bead are normalized by the surface coating thickness on the draw bead, both in micrometers ( $\mu\text{m}$ ). The pattern of the wear rate shown in this figure is similar to that in the mass-loss figure discussed previously. Although the surface coating at the wear band on the lower draw bead at the exit side appears to be worn off after ~50,000 drawings, no change in the structure and/or geometry/dimension of any bead is observable for any conditions in the present wear study. Therefore, from the viewpoint of structural integrity and robustness, CrN-coated S0050A appears durable and viable for draw beads and radii on draw dies used to stamp HD-GA DP500 parts.

The agreement between measured and predicted coating lives (i.e., a surface coating is 100% worn off) is excellent. The discrepancy during the wear process is because the wear predictor predicts only wearoff of the material from die surfaces rather than addition of any material from the sheet metal to the die surfaces. Namely, the predictor does not account for the mass gain and decrease in wear depth with increased drawing caused by material transfer from the sheet metal to the die surfaces, that is, the buildup and cold weld of zinc on the die surfaces from the sheet metal surfaces. Therefore, the predictor should be used primarily to predict the life of a die surface coating or to compare wear rates of different die surface coatings rather than to describe the intermediate wear process, unless the buildup on the die surfaces could be completely removed following each run, as sometimes occurred in stamping die maintenance—surface cleaning and polishing. Nevertheless, the predicted wear depth data agree very well with the trend line of the measured wear depth data throughout the wear process.

**Evolution of Microhardness of Draw Bead Surfaces.** The initial and final microhardness of draw bead surfaces on the wear bands is measured using a microhardness tester (Vickers), as plotted in Fig. 18 for the upper bead exit, lower bead entry, and lower bead exit sides, respectively, where the microhardness data are normalized by the initial value measured outside of the wear bands, both in Vickers. The trend shown in this figure corresponds very well to that in Fig. 8. Namely, after ~49,000 drawings, the microhardness drops to the lowest at the lower bead exit side as a result of the most severe surface roughening or wear at the lower bead exit side, followed by the lower bead entry side, and then the upper bead exit side.

The surface roughness measurements described previously are nondestructive and can be correlated to the wear amount (or wear depth or wear degree). While surface roughness measurements may be used to quantitatively assess die surface wear, the surface hardness

**Fig. 11** Evolution of surface roughness of draw beads—upper bead exit side (scale in mm)

measurements, however, may provide only a confirmation of the wear and a comparison of the wear degrees for different surface coatings, surface treatments, or surface locations, depending on the measurement technique (indentation or impedance) and/or load used (smaller loads for thinner surface coating films). Particularly, the Vickers hardness tests are destructive due to the microindentation and thus can be used only after the completion of the entire wear study. Therefore, no intermediate data or info could be obtained without damaging the surfaces of interest.

It should be noted that, in the present study, the load used in the microhardness tests may be toward the high end, and hence, both the initial and final microhardness values may be underestimated as compared to those measured at lower loads. Accordingly, the data in this figure should be used for comparison purposes rather than absolute quantitative assessment.

**Effects of Die Materials on Friction and Wear Behavior.** Friction and wear studies on various die materials (S0050A, D2, M2), either

bare, treated (ionitrided), or coated with various die surface coatings (chromium, CrN, CrC, WC, MoS<sub>2</sub>, thermal-diffusion VC), reveal that surface friction and wear behavior are dictated by the surface coating properties, such as hardness and roughness, whereas the bulk material properties of the dies have a negligible effect on surface behavior. The harder and smoother the die surfaces (bare, treated, or coated), the less the friction and the lower the wear rate of the die surfaces. These experimental and testing data were incorporated into the database of the die-wear prediction software developed in this work, as described previously.

The details of widely used surface treatment techniques and processes, such as physical vapor deposition, chemical vapor deposition, and thermal spray, can be found in Ref 2 and 3.

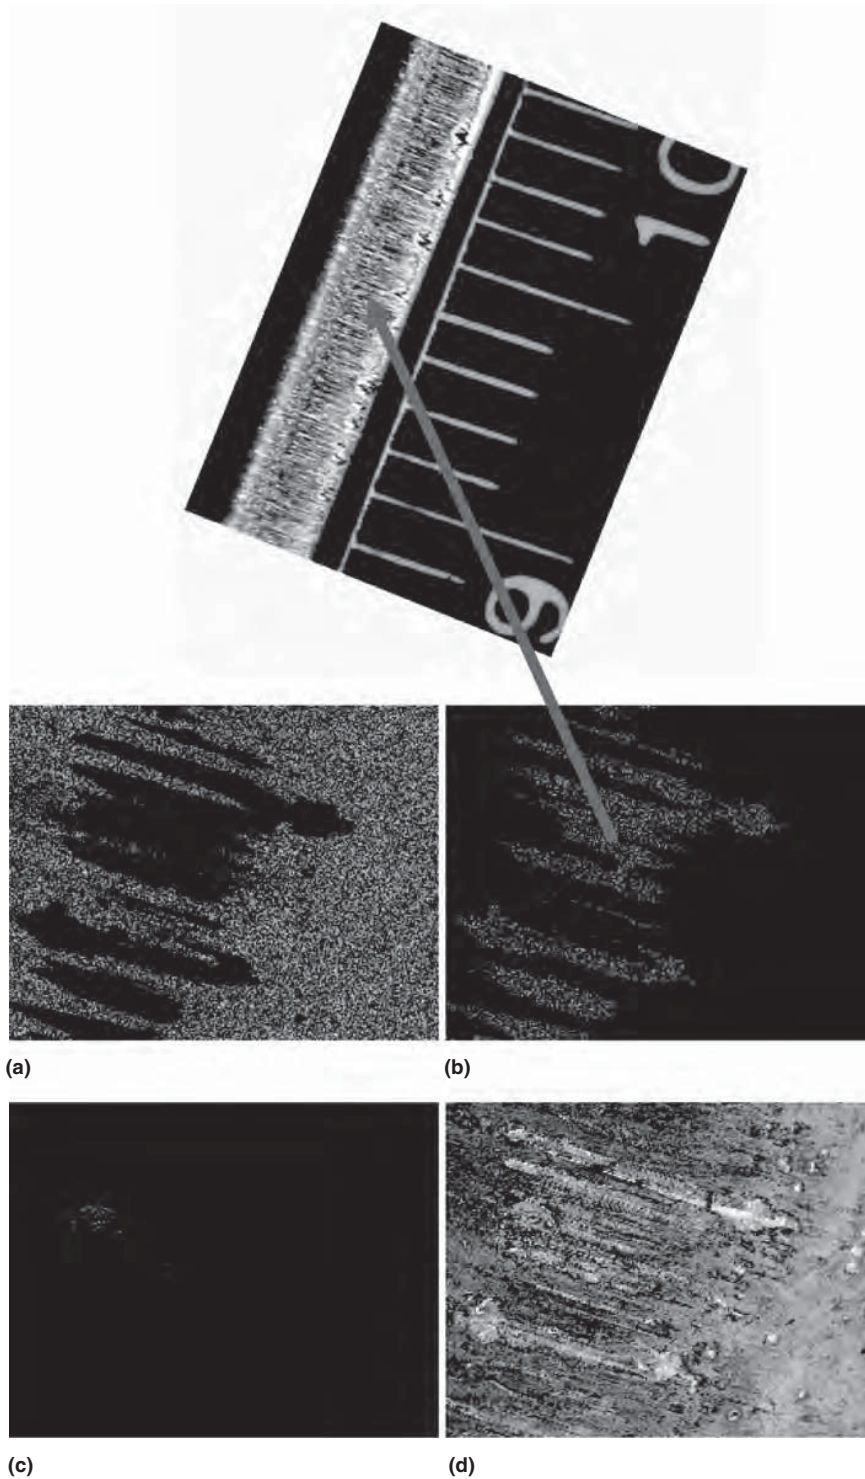

## Summary and Conclusions

Extensive wear tests using novel measurement techniques were conducted at the labs of

Ford Motor Company as part of a verification program for a die-wear predictor based on a linear theoretical model invented by the author (Ref 1). This extensive effort has improved the understanding of the effects of various factors on die wear rate, as outlined in this article. A series of friction tests and extensive wear tests have been completed in the labs of Ford Motor Company on mild steels and HSS with various surface coatings (EG, HD-GI, HD-GA) and different die materials (S0050A, D2, M2), either bare, treated (ionitrided), or coated with various die surface coatings (chromium, CrN, CrC, WC, MoS<sub>2</sub>, thermal-diffusion VC) during the period from 2003 to early 2005. Several novel techniques have been developed to directly measure die wear, using advanced measurement instruments at the Ford labs and to quantify die wear as a function of drawing. The detailed lab studies include characterization of the surface conditions of both the sheet metal and draw dies/beads over the number of drawings, measurements of the temperatures and roughness of both the draw beads and sheet metal over the number of drawings, quantification of material transfer and die buildup with drawing, measurements of drawing/binder forces and die wear as a function of drawing, and measurements of the initial and final microhardness of the draw bead surfaces. The findings from the lab wear tests are summarized as follows:

- Die surface roughening at contact areas to the sheet metal is rapid during the initial stage of die wear and then follows a roller-coaster pattern. The die surface roughening accelerates dramatically beyond the point where the die surface becomes rougher than the sheet metal surface. When the die surface becomes approximately three-times rougher than the sheet metal surface, the die surface coating approaches the end of its life, and hence, a die surface treatment should be rendered to avoid excess surface galling and dimensional instability of the stamped parts. The female bead surface roughness in the exit contact area should be used to determine when a die surface treatment is necessary.
- During the early stage of die wear, the die/bead surfaces are roughened at the contact areas with the sheet metal. The loose zinc particles from the softer sheet metal surfaces are sheared off by asperities on the harder die/bead surfaces. Some of the zinc particles are transferred to the die/bead surfaces on the contact areas, where they accumulate and lower the roughness of the die/bead surfaces. When the particles are accumulated to the extent that they change the local contact pressures at certain regions, the local contact pressures may be high enough to shear off microparticles from the die/bead surface asperities, causing collapse of the accumulated zinc particles and peeling off, along with some die/bead surface particles that they are welded to. This leads to roughening of the

**Fig. 12** SEM micrographs of wear band on lower bead. (a) Chromium map. (b) Iron map. (c) Zinc map. (d) Secondary electron image after ~49,000 drawings

die/bead surfaces at the contact areas. These loose particles may transfer to the sheet metal surfaces, roughening the sheet metal surfaces. The thousands of repeats of this particle-transfer process cause the grooves to become

deeper and wider on both the die/bead and sheet metal surfaces, that is, wear. This detailed adhesive wear mechanism explains the roller-coaster behavior of die surface roughness, the zinc buildup on die surfaces,

the die surface mass loss, and the die surface wear depth with increased drawing.

- Drawing force rises sharply in the early stage of die wear as a result of rapid die surface roughening. Then, its increase over drawing becomes more gradual or slower, with a large amount of scatters or oscillations due to variations or instabilities caused by material transfer during adhesive wear.
- The effects of surface roughness and material buildup on interfacial friction do not appear linear. Surface roughness seems to dictate interfacial friction behavior before the die/bead surface becomes rougher than the sheet metal. Beyond this point, the effect of material buildup becomes more and more important, and material buildup on the die/draw beads may function as a solid lubricant at the interface. Consequently, where material buildup on the die/beads peaks, the interfacial friction is lower, while where material buildup on the die/beads drops, the interfacial friction is higher in spite of the lower bead surface roughness.
- The surface temperature of the sheet metal is much higher than the draw die/bead surface temperatures over the majority of the drawing process. The surface temperatures of the draw die/beads increase virtually linearly with the number of drawings, whereas the surface temperature of the sheet metal increases with the number of drawings virtually exponentially in the early stage, and then the increase becomes more gradual, with large scatters in a roller-coaster fashion with further drawing due to the instability induced by typical adhesive wear. The evolution of the sheet metal surface temperature is influenced by sheet metal surface roughness, the resultant interfacial friction, and the resultant friction-induced heat. The bead temperatures are higher at the exit side than the entry side as a result of higher contact pressure and work hardening, which generate more heat that is transferred to the draw beads at the exit side.
- The rise of the temperatures of the draw die/beads and sheet metal with increasing drawing may be attributed to two factors: metal-deformation-induced heat and friction-induced heat. The heat generated during deformation of the sheet metal increases the temperature of the metal, but only a portion of this heat is transferred across the metal-die interface to the draw die/beads. If the friction-induced heat at the metal-die interface would be equally dissipated into the sheet metal and draw die/beads, the much higher surface temperature of the sheet metal suggests that (1) the metal-deformation-generated heat is more pronounced than the friction-induced heat; and/or (2) only a small portion of the metal-deformation-generated heat is transferred from the sheet metal to the draw die/beads via convection and due to the lower thermal conductivity of the surface coating on the draw die/beads compared to that of the sheet metal or its coating; and/or (3) the larger volume of the draw die/beads,

**Fig. 13** Evolution of material buildup per sheet metal sample on/in draw beads, normalized by HD-GA coating weight on sheet metal surface

**Fig. 14** Evolution of drawing force, normalized by binder force

compared to that of a sheet metal, functions as a heat sink; that is, more heat is conducted into the volume from the surface, leading to the lower surface temperature of the die/beads than that of the sheet metal.

- With increasing die wear, the die surface hardness drops. While surface roughness measurements may be used to quantitatively assess die surface wear, the surface hardness measurements, however, may provide only a

confirmation of the wear and a comparison of the wear degrees for different surface coatings, surface treatments, or surface locations, depending on the measurement technique and/or load used. In particular, the Vickers hardness tests are destructive due to the microindentation and thus can be used only after the completion of a wear study without damaging the surfaces of interest.

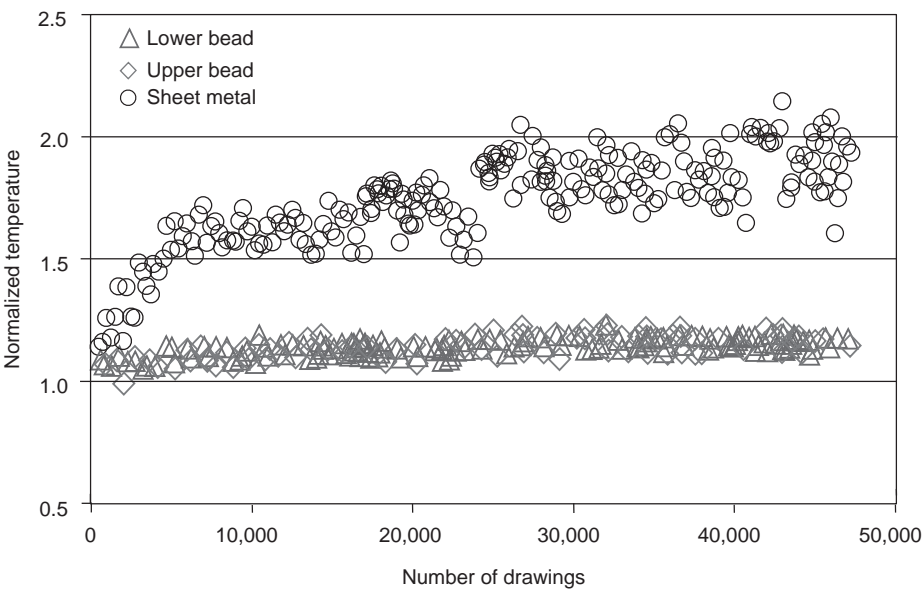

In summary, these lab tests advanced the understanding of the effects of various factors on die wear rate. The lab wear tests provide a comprehensive database and material support to the fact that some conventional and existing commercial casting materials may be used to stamp HSS parts for acceptable die life and part quality in high-volume productions with robust die structure designs and appropriate die surface coatings. While advanced die surface treatments and/or coatings over low-cost castings may provide a viable cost solution for HSS stamping dies, further studies on cost-effective tribology solutions and thermal management are underway to enable high-volume stamping/forming productions of AHSS or UHSS, such as DP780, DP980, and DP1250 or beyond.

## ACKNOWLEDGMENTS

The author is grateful to Mr. Milo Gaynier and Mr. Hiro Sugiura (Ford Motor Company) for their sustained support of this long-term project and to Mr. John Eidt (Ford Motor Company) for his financial support. She would like to thank Dr. Susan Ward, Dr. William Donlon, Mr. Steven Simko, Mr. Ron Cooper, and Mr. Larry Reatherford (Ford Motor Company) for the use of their labs and the associated technical assistance. Finally, she would also like to thank Mr. Tom Baron (Ford Motor Company) and Delray Steel Casting Inc. for draw bead material and preparation; Ion Bond Inc., International Coatings, Inc., Praxair, and Empire Hard Chrome, Inc. for draw bead coatings; and United States Steel Corporation for the contribution of sheet steels for Ford lab wear tests.

# Indirect Nondestructive Measurements of Die Wear in Stamping Productions

Huimin Liu, Materials Surface Engineering and Testing, Ford Motor Company\*  
Sriram Sadagopan, Mittal Steel USA R&D

WEAR OF DRAW DIES and draw beads occurs as a result of high, localized contact pressure and friction between sheet metal and die surfaces, among others. Die wear may take place in various forms, such as changes in radii, peeling off or wearing out of surface coatings, scratches, galling, and/or pitting of the die surfaces. In stamping operations of sheet metals for automotive body-in-white (BIW) parts, automotive original equipment manufacturers (OEMs) have been concerned about stamping advanced high-strength steels (AHSS) and ultrahigh-strength steels because extremely high contact pressure and heat generated due to deformation of the sheet steels may accelerate die wear, leading to instability in part dimensions and degradation of part surface quality and part safety. In an effort to improve the fuel economy of vehicles, various approaches have evolved in the past decades. Among them, the use of high-strength steels (HSS) for BIW parts has proven to be an effective means of reducing vehicle weight for similar or superior vehicle performance as thicker-gage mild steel parts. More recently, AHSS have attracted increasing attention for emerging applications in vehicle body structures.

This article describes novel techniques for indirect nondestructive measurements of die wear in stamping productions. The draw die wear monitored and quantified in high-volume stamping productions of HSS parts is presented along with detailed discussions of plant findings. This effort was a joint project of Ford Motor Company and Mittal Steel USA. A die-wear monitoring program was set up at Ford stamping plants to collect field data throughout the period from 2003 to 2006. Three sets of dies were selected, all for hot dip (HD) galvanized (GI) dual-phase (DP) 600 (DP600) parts of 1.4 to 1.9 mm (0.06 to 0.07 in.) in thickness. The novel techniques developed earlier by the Ford and Mittal Steel team for indirect nondestructive measurements of draw die wear during stamping

production of an electrogalvanized (EG) DP500 part were further enhanced for acquiring and extracting draw die and bead geometry and surface conditions at selected locations during high-volume production of the DP600 parts. This was in conjunction with laboratory wear tests to verify a theoretical formula of die wear (Ref 1). The laboratory tests are described in a separate Handbook Online article, "Prediction and Direct Measurements of Die Wear in Stamping Processes."

## Indirect Nondestructive Measurements—Plant Monitoring

The measurement techniques for die wear can be classified into the following two categories:

- Direct measurements—lab techniques
- Indirect nondestructive measurements—plant monitoring

The details of the plant monitoring techniques are described in this article, along with comprehensive discussions on the measured wear data. The direct lab measurement techniques are presented in a separate Handbook Online article, "Prediction and Direct Measurements of Die Wear in Stamping Processes," along with extensive wear test results.

The monitoring of die wear at Ford stamping plants includes measurements, quantifications, examinations, and/or observations of the following variables:

- Surface roughness of die surfaces at selected locations using a portable two-dimensional (2-D) surface profilometer
- Surface hardness of die surfaces at predefined locations using a portable hardness tester

- Die and bead geometry/contour and surface conditions at selected locations using a novel impression technique coupled with analytical instruments
- Macro surface defects and zinc buildup on die surfaces by visual observations

The novel impression technique was developed by the Ford and Mittal Steel team because direct measurements of volume or mass loss of a die over time, that is, die wear, are not presently feasible due to the large sizes of stamping dies in automotive applications. A surface replication method appears to be the only practical approach to determine possible geometry changes on the die surfaces over time.

In the impression technique, surface replication is conducted using Technovit 3040 fast-setting resin. The Technovit resin is chosen because of its quick-setting properties and its excellent replication of surface conditions. The creation of surface impressions of dies and/or beads includes the following procedures:

- *Selection of locations for wear monitoring:* Locations for wear monitoring must be selected based on higher tendency for wear, since it is impractical to examine the entire surface of a die. This can be assessed by visual inspection of the die surfaces and identification of regions of longer sliding distance in comparison to the rest of the die. It may also be necessary to examine regions of higher forming severity, such as at draw corners, punch and die radii, and where wrinkles are observed.
- *Creation of molds to contain the resin compound:* In order to contain the liquid resin, molds must be built at selected locations. In principle, any suitable epoxy can be used for molding. However, for repeatable and consistent measurements, it is recommended to create a permanent or semipermanent mold with straight walls using some

\* Dr. Huimin Liu was Supervisor of Materials Surface Engineering and Testing, Stamping and Die Engineering, SBU, Ford Motor Company. She is currently Group Leader of Stack Materials, Fuel Cell Research and Technology, R&AE, Ford Motor Company.

characteristic die features for quick and easy locating to ensure consistent location every time an impression is made (Fig. 1).

- *Creation of surface impressions by casting Technovit resin in the molds:* The liquid resin compound is prepared by mixing a powder with a liquid (at a volume ratio of 2 to 1) that is supplied by the manufacturer. Once the solution is prepared, it is poured immediately into a mold built for a selected location on a die. Depending on ambient temperature, the setting time for the resin ranges from 10 to 15 min. Figure 1(a) shows the liquid resin inside a temporary mold at a selected location on a die.
- *Analysis of surface impressions:* Once the resin is completely solidified, it is released from the die surface and the mold. It is found that use of a release agent for removal of the cast impression is not necessary. After the impressions at all predefined locations are taken, the replicated surfaces are characterized by surface analyses and roughness evaluation of the cast impressions using a three-dimensional (3-D) optical scanner (ATOS) and surface profilometer (Zygo), respectively, at Mittal Steel's USA R&D Center. For accurate surface measurements, the impressions are machined to obtain consistent reference surfaces for sample locations on the measurement table.

### Indirect Measurements of Die Wear at Stamping Plants

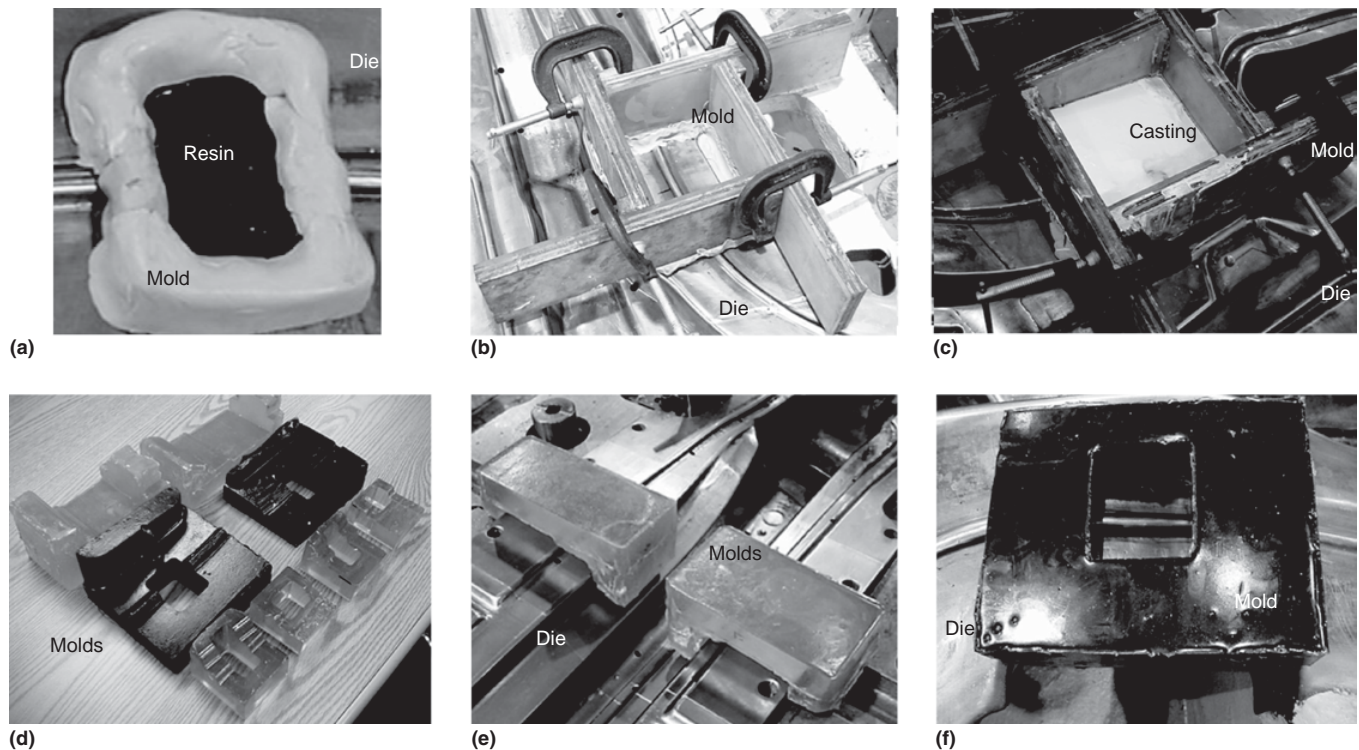

As noted, direct measurement or examination of die wear during stamping operations in a production environment is extremely difficult, if not impossible. Accordingly, Ford Motor Company and Mittal Steel initiated a joint project to monitor die wear and collect field data at Ford stamping plants throughout the period from 2003 to 2006. Three sets of dies were selected, all for HD-GI DP600 parts, ranging from 1.4 to 1.9 mm (0.06 to 0.07 in.) in thickness. A novel technique developed earlier by the Ford and Mittal Steel team for indirect nondestructive measurements of draw die wear during stamping production of an EG DP500 part was further enhanced for acquiring and extracting draw die and bead geometry and surface conditions at selected locations during high-volume production of the DP600 parts. The measured data are subsequently discussed in detail, with emphasis on a HD-GI DP600 part of 1.4 mm (0.06 in.) on whose draw dies several different surface coatings were tested during normal stamping productions. Some photos of the dies, measurement locations, and surface conditions after a certain number of drawings (number of hits) are depicted in Fig. 2 and 3.

As shown in Fig. 3, the draw die surface condition after thermal-diffusion (TD) VC treatment

remained excellent even after some 417,700 hits. There was no remarkable roughening, chip, crack, pit, score, or scratch. In addition, buildup of sheet metal coating debris on the draw die was much less compared to those on the untreated die surfaces. The structural integrity and geometry profile of the die did not show any visible change over time, as observed by the unaided eye.

**Roughness of die surfaces at selected locations** was measured using a portable 2-D surface profilometer in Ford stamping plants following a certain number of production runs. The surface roughness conditions were also extracted using the Zygo surface profilometer from the surface impressions made at the same locations on the same dies. The evolution of surface roughness ( $R_a$ ) at the four selected locations on the draw dies depicted in Fig. 2 and 3 is summarized in Fig. 4, where the roughness of the die surfaces is normalized by the roughness of the sheet metal (HD-GI DP600 of 1.4 mm, or 0.06 in.), both in micrometers ( $\mu\text{m}$ ).

In Fig. 4 and the following discussions, location A is on the female draw die (equivalent to the lower draw die used in Ford lab's wear tests); location C is at the other end of the female draw die, whereas locations B and D are the mating locations of A and C on the male draw die (equivalent to the upper draw die used in Ford lab's wear tests). The male draw die surfaces were only chromium-plated, whereas the female draw die surfaces were treated by or coated with

different coatings, which made this set of dies a perfect candidate for comparing various surface treatments or coatings.

Figure 4 shows the roughening or wear of the die surfaces with increasing number of drawings (number of hits):

- At location A, the chromium-plated die surface was roughened relatively rapidly after < 35,000 drawings. The die surface was then  $\text{MoS}_2$  sealed to improve the surface finish. It was observed that the  $\text{MoS}_2$ -sealed chromium coating was worn off after some 78,000 drawings. The female draw die was rebuilt with inserts whose surfaces were treated by thermal diffusion for VC coating (TD VC). The surface roughness was reduced significantly by the TD VC treatment and the associated postprocessing. The TD VC surface roughness remained virtually unchanged (no roughening) for more than 87,000 hits following the TD treatment as compared to the almost doubled roughness at location B after the same number of hits. For an additional > 145,000 hits, the surface roughness at location A barely doubled. These data revealed that the surface roughening rate was  $2.55 \times 10^{-6}$  per hit on the TD VC surface (location A) as compared to  $1.70 \times 10^{-5}$  per hit on the chromium-plated surface (location B).

**Fig. 3** Evolution of surface conditions on a draw die for a hot dip galvanized dual-phase 600 part of 1.4 mm (0.06 in.). (a) After ~35,000 drawings. Chromium plated. (b) After ~106,200 drawings. Thermal-diffusion (TD) VC treated. (c) and (d) Slightly roughened radii after ~417,700 drawings. TD VC treated

**Fig. 4** Evolution of normalized surface roughness at predefined locations on draw dies for a hot dip galvanized dual-phase 600 part of 1.4 mm (0.06 in.). TD, thermal diffusion

Correspondingly, the wear rate of the die surfaces should be 6 to 7 times lower after TD VC treatment than after chromium plating.

- At location C, the die surface became very smooth after the TD VC treatment. The surface roughness was doubled following more than 87,000 hits, whereas the surface roughness was doubled on the chromium-plated surface (location D) as well for the same number of hits. However, the roughening rate was distinctly different: On the TD VC surface it was  $6.22 \times 10^{-6}$  per hit (location C) as compared to  $2.32 \times 10^{-5}$  per hit on the chromium-plated surface (location D). Accordingly, the wear rate of the die surfaces should be 3 to 4 times lower after TD VC treatment than after chromium plating.

Based on these data, it appears to be safe to conclude that the wear rate of the die surfaces after TD VC treatment should be at least 3 to 4 times lower than after chromium plating.

A comparison of the direct and indirect measurements of surface roughness ( $R_a$ ) is given in Fig. 5 for the draw die illustrated in Fig. 3, where the roughness of the die surfaces is normalized by the roughness of the sheet metal (HD-GI DP600 of 1.4 mm, or 0.06 in.), both in micrometers ( $\mu\text{m}$ ).

It appears that the smaller the roughness, the larger the variations in the directly measured roughness. As expected, the indirectly measured roughness values are lower than the directly measured ones for chromium-plated or MoS<sub>2</sub>-sealed chromium surfaces. It is hypothesized that the fast-cure resin could plausibly not completely penetrate into the fine roughness valleys, whereas the very hard and small diamond tip on the probe of the surface profilometer could follow the surface roughness in a closer fashion. For both locations A and C,

however, the indirectly measured roughness values are slightly higher than the directly measured ones for the TD VC-treated surfaces at < 400,000 hits. Plausibly, this may be due to the better wetting of the fast-cure resin on the TD VC surfaces than the chromium-plated or MoS<sub>2</sub>-sealed chromium surfaces. Beyond 400,000 hits, the indirectly measured roughness values become lower than the directly measured ones. Nevertheless, the decent agreement between the directly and indirectly measured roughness values and their trends (roller-coaster patterns) is encouraging, considering that the tiny measurement spots are most likely different, although close enough, in the direct and indirect measurements, in addition to the noises typical in the plants environment. Thus, the roughness data directly measured on the die surfaces in the stamping plants as well as extracted from the die surface impressions should be used to supplement and confirm each other.

To minimize the noises or variations in surface roughness measurements, a suitable cleaning material (perhaps a solvent) and the associated cleaning procedure should be individually developed and implemented for the respective die surface and/or coating of interest, which would promote consistency in surface wetting conditions and, at the same time, not damage the surface and/or coating over time.

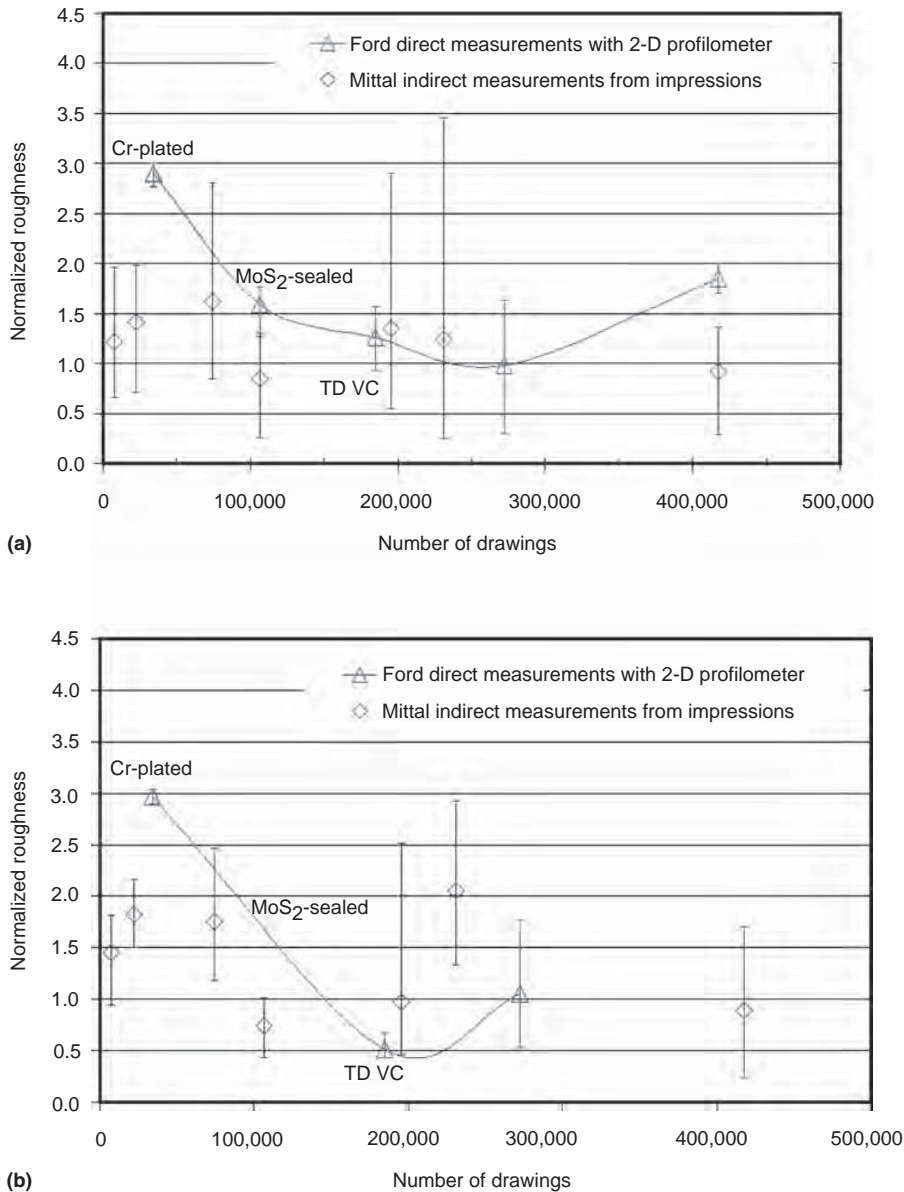

**Hardness of die surfaces at predefined locations** was measured using a portable hardness tester in Ford stamping plants following a certain number of production runs. The evolution of surface hardness at four selected locations (A to D) on the draw dies depicted in Fig. 2 and 3 is summarized in Fig. 6, where the hardness of the die surfaces is normalized by the nominal hardness of a chromium-plated

surface or a chromium coating, both in Rockwell C.

It can be seen from Fig. 6 that:

- The variations of the hardness readings on chromium-plated surfaces appeared larger than on TD VC-treated surfaces.
- At locations A and C, the first readings appeared to be a weighted average of the hardness of the flame-hardened die surfaces and the remaining chromium coating, since a certain amount of chromium coating was worn off after 34,419 hits. Following the MoS<sub>2</sub> seal and TD VC treatment, the hardness readings were significantly lower than the nominal hardness values of the coatings. This is because the surface treatment may have tempered the die substrate material, leading to a reduced hardness. Also, the hardness tester used applies a relatively high load and deep indent, which may have caused penetration of the measurement ball through the very thin coating layer, resulting in a reading of the die substrate hardness rather than the coating hardness. Therefore, these hardness readings are not the true values for the MoS<sub>2</sub>-sealed chromium coating or TD VC coating and hence cannot be used to predict the life of the MoS<sub>2</sub>-sealed chromium coating or TD VC coating, although they can confirm the trend of the surface condition evolution. Namely, the slightly lowered hardness at location A and the virtually constant hardness at location C following the TD VC treatment suggest that the surface coating was roughened (worn off) slightly at location A, and the surface conditions remained virtually unchanged or roughened slightly at location C. These results are consistent with the trends in the roughness evolution discussed previously and thus confirm the findings from the roughness monitoring. It should be noted that the changes in the hardness values following the TD VC treatments at locations A and C are small and well within the range of normal variations. Thus, the hardness can be considered virtually unchanged, further confirming the very low roughening rate or wear rate of the TD VC surfaces. The virtually constant hardness also suggested that the mechanical properties of TD VC coatings are uniform or consistent over the coated surfaces, because the hardness measurements were not done at the exact same spots each time.
- At locations B and D, the hardness readings showed a slight increase with production runs. This trend was unexpected. However, considering that the hardness measurements were not done at the exact same spots each time, the changes in the hardness readings may be due to inherent variations in the mechanical properties of the surfaces. More readings over production runs in the future will help to remove the uncertainty.

To acquire the true surface hardness values of thin-film coatings on stamping dies in

**Fig. 5** Comparison of directly and indirectly measured surface roughness at (a) location A and (b) location C on draw die for a hot dip galvanized dual-phase 600 part of 1.4 mm (0.06 in.). TD, thermal diffusion

stamping plants, a portable microhardness tester must be used. Unfortunately, the currently available portable microhardness testers exhibit some limitations in the measurable hardness range, accuracy, and operation conditions. Further research and development efforts are needed for accurate, fast, and easy nondestructive microhardness measurements of thin coatings in the plant production environment.

**Geometry Contour of Die Radii, Steps, and/or Beads.** The geometry contours/profiles of die surfaces at selected locations (radii and steps) were captured using the novel impression technique in Ford stamping plants following a certain number of production runs. The

geometry profiles were then extracted from the impression castings using the 3-D optical scanner ATOS. The evolution of the geometry profiles at four selected locations (A to D) on the draw dies depicted in Fig. 2 and 3 is summarized in Fig. 7, where the two dimensions are normalized by the depth of the male step bead, both in millimeters (mm).

It can be seen from Fig. 7 that:

- Based on typical engineering tolerance for stamping dies, the geometry profiles at locations A to D remained virtually unchanged from the beginning of production throughout > 400,000 hits.

- The maximum dimensional offsets at locations A and D were < 1 mm (0.04 in.), at location B < 2 mm (0.08 in.), and at location C < 0.8 mm (0.03 in.), well within measurement tolerance. These dimensional offsets may have been caused by the variations in aligning the machined impression castings in the fixture of the 3-D optical scanner and the associated offsets of the reference surfaces for sample locations on the measurement table. The obvious dimensional offsets at location A between the two profile groups extracted from the old temporary molds and the new permanent molds were apparently due to the offset in the reference surfaces. This issue was prevented to a great extent at locations B to D.
- The new molds, which are the permanent molds, yielded more consistent readings than the old temporary molds that were used in the early stage of the plant monitoring processes. Therefore, using the permanent molds in future plant monitoring programs will significantly improve the accuracy of the profile digitization and completely eliminate the dimensional offsets due to slight misalignment of reference surfaces.
- The advanced die surface coating significantly reduced die wear and subsequently led to consistent die geometry profiles or undetectable change in die, bead, and step radii over extended time during the HSS stamping production.

**Macro Surface Defects and Zinc Buildup on Die Surfaces.** For the HD-GI DP600 part of 1.4 mm (0.06 in.) discussed previously and a HD-GI DP600 part of 1.9 mm (0.08 in.), both draw dies were treated and coated with advanced surface coatings. Accordingly, no macro surface defects (chip, crack, pit, score, or scratch) were observed during the course of stamping production and after successful continuous production runs for more than 2 years.

Some mild zinc buildup was observed on the die surfaces by visual examinations following a couple of thousand continuous hits, as illustrated in Fig. 8. Evidently, the advanced die surface coatings and the associated superior surface finishes minimized the HSS part surface galling, as proved by the minimal zinc buildup on the die surfaces.

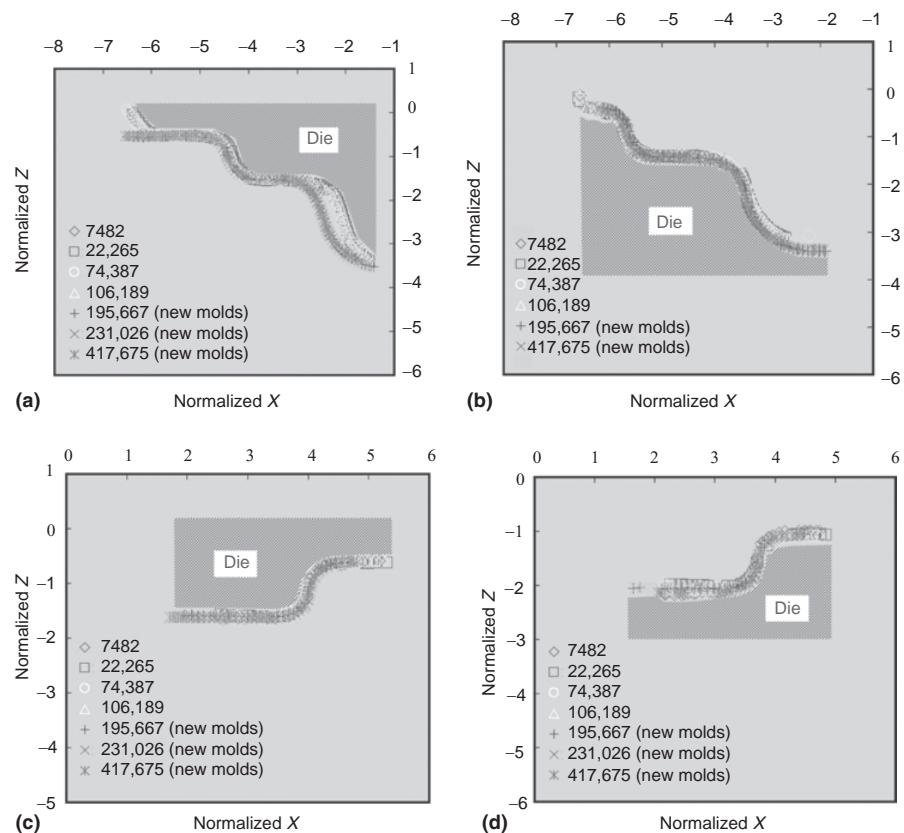

### Comparison Between Predicted and Measured Die Wear Rates

Figure 9 depicts the predicted (Ref 1) wear rates of various die surfaces and lubrication conditions for a HD-GI DP600 part of 1.4 mm (0.06 in.), along with the wear rates at the four locations (A to D) extracted from the measured roughness data (Fig. 4) acquired during the plant monitoring process on the dies illustrated in Fig. 2 and 3, as detailed previously. All the wear-rate data in micrometers per hit ( $\mu\text{m}/\text{hit}$ ) are normalized by the roughness of the sheet metal (HD-GI DP600 of 1.4 mm, or 0.06 in.)

**Fig. 6** Evolution of normalized surface hardness at predefined locations on draw dies for a hot dip galvanized dual-phase 600 part of 1.4 mm (0.06 in.). TD, thermal diffusion

**Fig. 7** Evolution of normalized surface contours/profiles at predefined locations on draw dies for a hot dip galvanized dual-phase 600 part of 1.4 mm (0.06 in.). (a) Location A. (b) Location B. (c) Location C. (d) Location D

in micrometers ( $\mu\text{m}$ ), reducing the unit for the wear rates to per hit (/hit). In the prediction calculations, the nominal values of hardness were used for ionitriding, chromium, CrN, and TD VC surfaces, whereas for cast iron, the typical hardness of an untreated gray iron (G3500 without flame hardening or induction hardening) was taken into account. In addition, the actual stamping process parameters, sheet metal properties, and die/step geometry parameters for stamping the HD-GI DP600 part of 1.4 mm (0.06 in.) in the plant production runs were used in the prediction calculations. The details of widely used surface treatment techniques and processes, such as physical vapor deposition, chemical vapor deposition, and thermal spray, can be found in Ref 2 and 3.

As shown in Fig. 9, the agreement between the predicted and the indirectly measured wear rates is excellent for the TD VC surfaces, whereas the predictor slightly overpredicts the wear rates on the chromium surfaces as compared to the plant monitoring data. Overall, the agreement between the predicted and the indirectly measured wear rates is good, considering the variations in measurements in the plant environment and the inadequacy of the predictor in predicting zinc buildup on the roughened chromium surfaces. Note that the zinc buildup is much more on the roughened chromium surfaces than on the smooth TD VC surfaces. In addition, the wear rates derived from the indirect measurements are approximations based on the roughening rates and hence are accurate to at least the order of magnitude as a result of the limitations in the currently available measurement instruments usable in the plant environment. Accordingly, the die wear predictor (Ref 1) is fully verified and validated by the long-term plant monitoring results.

In addition, the data calculated using the predictor, as depicted in Fig. 9, show that:

- The TD VC-treated die surfaces last the longest, followed by the CrN, chromium, ionitrided, and untreated cast iron surfaces.
- The TD VC-treated die surfaces could withstand at least two million hits for stamping the HD-GI DP600 part of 1.4 mm (0.06 in.).
- Using improved lubrication, such as a dry-film lubricant, could significantly lower the wear rate and extend the die surface life.

## Summary and Conclusions

Ford Motor Company has teamed up with Mittal Steel in a joint project to monitor die wear in HSS stamping productions at Ford stamping plants throughout the period from 2003 to 2006. Three sets of dies have been selected, all for HD-GI DP600 parts of 1.4 to 1.9 mm (0.06 to 0.07 in.) in thickness. Several novel techniques developed earlier by the Ford and Mittal Steel team for indirect nondestructive measurements of draw die wear during stamping production of an EG DP500 part have been optimized

**Fig. 8** Mild zinc buildup on die surfaces for hot dip galvanized dual-phase 600 parts of (a) 1.4 mm (0.06 in.) and (b) 1.9 mm (0.08 in.)

**Fig. 9** Normalized wear rates predicted and quantified based on plant monitoring data for a hot dip galvanized dual-phase 600 part of 1.4 mm (0.06 in.). IN, ionitriding; TD, thermal diffusion

for acquiring and extracting draw die and bead geometry and surface conditions at selected locations during high-volume production of the DP600 parts. The following findings have been derived from the plant monitoring programs:

- The predominant form of die wear observed during high-volume stamping production of HSS parts was adhesive wear, that is, roughening of the die surface or coating. No change in die radii/steps or profiles was detected where an appropriate surface coating or treatment was applied.

- The wear rate of the die surfaces after TD VC treatment appeared to be at least 3 to 4 times lower than after chromium plating.
- The hardness readings were virtually constant and more uniform on the TD VC-treated surfaces than the chromium-plated surfaces. The hardness readings on the thin-film coatings with the currently available hardness testers should be used for comparison and confirmation purposes only.
- The TD VC-treated die surfaces could withstand at least two million hits for stamping the HD-GI DP600 part of 1.4 mm (0.06 in.).

- The TD VC-treated die surfaces last the longest, followed by the CrN, chromium, ionitrided, and untreated cast iron surfaces.
- Using improved lubrication, such as a dry-film lubricant, could significantly lower the wear rate and extend the die surface life.
- The advanced die surface coatings (TD VC and CrN) significantly reduced die wear and minimized the HSS part surface galling, as proved by the minimal zinc buildup on the die surfaces, and subsequently led to consistent die geometry profiles or undetectable change in die, bead, and step radii over extended time during the HSS stamping production.
- The die-wear rates calculated using the Ford die-wear predictor (Ref 1) were in good agreement with the data indirectly measured during the plant monitoring. Accordingly, the die-wear predictor is fully verified and validated by the long-term plant monitoring results.

It is encouraging to have discovered that some conventional and existing commercial casting materials may be used to stamp HSS parts for acceptable die life and part quality in high-volume productions with robust die structure designs and advanced die surface coatings. The advanced die surface treatments and/or coatings over low-cost castings may provide a viable cost solution for HSS stamping dies.

#### ACKNOWLEDGMENTS

The author (Dr. Huimin Liu) is grateful to Mr. Milo Gaynier and Mr. Hiro Sugiura (Ford Motor Company) for their sustained support of this long-term project and to Mr. John Eidt (Ford Motor Company) for his financial support. She appreciates the support from Mr. Lou Stefanovic, Mr. Pearl St. Clair, and Mr. Gary Urbanchock (Ford Motor Company), who enabled the long-term plant monitoring programs.

The consistent collaboration and reliable measurements and analyses from the technical team at Mittal Steel as well as the critical support from the management team and Dr. Benda Yan at Mittal Steel are greatly appreciated.

# Bending of Sheet Metal

BENDING is a common metalworking operation to create localized deformation in sheet (or blanks), plates, sections, tubes, and wires. Bending occurs from stressing a workpiece in a localized area, and it results in non-uniform deformation (contraction and elongation) within the cross-sectional area of bending. Because of these inhomogeneities, analyses of stress strain distributions are of utmost importance when evaluating bending conditions (see the section “Stress-Strain Behavior in Bending” in this article).

Bending is done in various types of operations and machines such as press brakes or four-slide machines. Plates and sections are often bent in three-roll benders into complete circles. Roll forming is another type of bending operation that allows mass production of two-dimensional corrugated sheet, architectural sections, and lock-seam and welded tubes. This article focuses on the bending of sheet metal along with some coverage on flanging. Bending a sheet along a curved line is termed flanging. Circular or other close-shaped flanges (collars) are mass produced in preparation for joining tubes and fasteners to sheet, as in heat exchangers. Limits are set by fracture in a stretch flange and by buckling in a shrink flange. Related processes are flanging and necking of tubes and cans, as on beverage cans.

## Bending Theory

The forces applied during bending are in opposite directions, just as in cutting of sheet metal. The bending forces, however, are spread farther apart, resulting in plastic distortion of metal without failure. The simplified sketches in Fig. 1 illustrate the forces applied during bending in V-dies, wiping dies, and U-dies. The latter two are more typical of high-production bending dies. The U-die is often referred to as a channel die. The spread of shear forces in a cutting die is equal to the clearance, which is usually approximately 10% of the sheet-metal thickness. The larger spread of bending forces is accomplished by using a clearance equal to the sheet metal thickness plus the radii used on the punch and die steels.

As the load is applied, the bending is similar to the deflection of a beam under load. The metal on

the outside of the bend radius becomes stretched or elongated from tensile stress, while metal on the inside of the bend radius is placed under a compressive stress. If failure or fracturing occurs during bending, it will occur at the outside bend surface. Wrinkling will occur on the inside surface of the bend. When the metal is stressed above its elastic limit, it acquires a permanent set. Some elasticity usually remains, however, so that the metal tends to “spring back” as the pressure of the punch is released. This springback is compensated for by overbending or by bottoming the metal. Bottoming must be done with care, because thickness variations may cause overloading of the press or cause injury to the die.

When the sheet slides over the die radius, a frictional force is generated at the points of contact (Fig. 2). Because the interface pressures are low (well below the flow stress of the workpiece material), contact is limited to the asperities, and the coefficient of friction can be quite high (Ref 1). If the die/workpiece combination is prone to adhesion, pickup develops. If the workpiece is covered with hard abrasives, die wear occurs. In either case, the workpiece becomes scored, and lubrication would be needed.

**Neutral Axis.** The neutral axis is the line of zero stress and strain in a bend with tension on one surface and compression on the other (Fig. 3). Before bending, the flat blank is of a certain length, and the length of the neutral axis is, of course, exactly equal to this original blank length. During bending, the outside surface of the sheet metal is increased in length, and the inside surface of the sheet metal is decreased in length, but the length of the neutral axis remains

the same. Because the neutral axis is a true representation of the original blank length, it is used for blank-development calculations.

When the blank is first being bent, the neutral axis is near the center of the sheet-metal thickness. As bending progresses, the neutral axis shifts toward the inside, or compression side, of the bend. Normally, the neutral axis is measured as a certain distance from the inside surface of the sheet metal at the bend area. Sheet metal thins slightly in the bend area, and the outside surface at the bend radius is not an accurate dimension. The inside surface bends tightly on the die-steel radius and is held to closer tolerances. Therefore, most parts are dimensioned with radii to the inside surface at all bends.

In bending of sheet metal, the distance from the inside surface to the neutral axis is usually approximately 40% of the thickness. Approximate positions of the axis for various thicknesses are shown in Fig. 4. Characteristics of the neutral axis are:

- If the sheet metal thickness is constant, the neutral axis shifts closer to the inside surface as the radius of bend is decreased.
- If the radius of bend is constant, the neutral axis shifts closer to the inside surface as the sheet metal thickness is increased.
- If the radius of bend and sheet metal thickness are constant, the neutral axis shifts closer to the inside surface as the degree of bend is increased.

Because the position of the neutral axis shifts for each variable listed, precise blank-size calculations are frequently difficult. Some alteration of

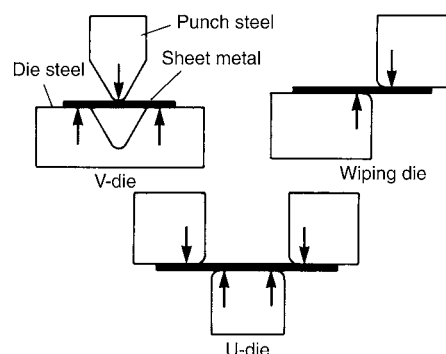

Fig. 1 Forces applied during bending

Fig. 2 Frictional stresses acting on sheet during bending

blank dimensions may be necessary after bending the first parts in the die.

**Metal Movement.** During production bending, one area of the blank is usually held

stationary by a pressure plate called a pad. The free blank area is then bent up or down to create the change in contour. The metal forced down or up by the punch moves through space to occupy a

new position. This metal movement through space is often called swinging and is a characteristic common only in bending operations. Such metal movement does not occur in embossing, stretch forming, or drawing of sheet metal. Illustrations of bending motions are presented in Fig. 5. In design of a bending die, the swinging action must be predicted so that no obstacles are placed in the way. Because of the metal movement, the larger area is usually held stationary, and the smaller blank area is moved by the punch.

**Springback.** Variations in bending stresses cause springback after bending. The largest tensile stress occurs in the outside surface metal at the bend. The tensile stress decreases toward the center of the sheet thickness and becomes zero at the neutral axis. The pie-shaped sketch in Fig. 6 depicts the changing tensile and compressive stresses in the bend zone. Because the tensile stresses go from zero at point 0 on the neutral axis to a maximum value at point X on the outside surface, the stress-strain curve developed by the standard tensile test may be used for an analysis of bending. For good bend design, the tensile stress at point X is less than the ultimate tensile strength, as shown. If tensile stress is greater than ultimate strength, the metal may fracture during bending.

The metal nearest the neutral axis has been stressed to values below the elastic limit. This metal creates a narrow elastic band on both sides of the neutral axis, as shown in Fig. 7. The metal farther away from the axis has been stressed beyond the yield strength, however, and has been plastically or permanently deformed. When the die opens, the elastic band tries to return to the original flat condition but cannot, due to restriction by the plastic deformation zones. Some slight return does occur as the elastic and plastic zones reach an equilibrium, and this return is known as springback.

Variables and their effects on springback are as follows:

- Harder sheet metals have greater degrees of springback due to a higher elastic limit.
- A sharper or smaller bend radius could cause tearing, due to higher stresses in the outside surface.
- As metal is bent through greater degrees of bend, the plastic zone is enlarged and springback is reduced for each degree of bend. Total springback is increased, however.

**Overcoming springback** is a major factor in forming operations and is described in more detail in the article "Springback" in this Volume. Several methods are used to overcome or counteract the effects of springback (Fig. 8). These are:

- Overbending
- Bottoming or setting
- Stretch bending

Sheet metal is often overbent an amount sufficient to produce the desired degree of bend or bend angle after springback.

**Fig. 3** Distribution of strain determined by the simple-beam theory. (a) Linear distribution for fiber elongations and contractions. (b) Distribution of engineering strain. (c) Distribution of true strain.  $R_n$ , radius of neutral axis;  $R_i$ , inner radius;  $R_o$ , outer radius

**Fig. 4** Positions of the neutral axis

**Overbending** (Fig. 9) may be accomplished by using cams, by decreasing the die clearance, or by setting the punch and die steels at a smaller angle than required in the case of a V-die. When the clearance is reduced below the sheet metal thickness, the burnishing action wipes the metal against an undersized punch or die steel.

**Bottoming or setting** consists of striking the metal severely at the radius area. This places the metal under high compressive stresses that set the metal past the yield strength. Bottoming is accomplished by placing a bead on the punch at the bend area. In a wiping die or U-die, the pad must bottom against the shoe or backing plate so that the punch may set the metal at the bend. It would be useless to bottom against the flat areas of sheet metal, because they are not stressed and

do not cause springback. Also, bottoming against these larger areas would require extremely high press tonnages. Bottoming must be carefully controlled when adjusting the press ram, or the forces involved will rise at a rapid rate. Also, if two blanks are accidentally placed in a bending die that bottoms, press or die breakage may result.

**Stretch bending** consists of stretching the blank so that all the metal is stressed past the yield strength. The blank is then forced over the punch to obtain the desired contour. This prestressing before bending results in very little springback. Only relatively large radii are bent by this method, because sharp radii would take the prestressed metal beyond the ultimate tensile strength. The sheet metal must be uniform in

strength. Any weak spots or defects will certainly cause failure. Stretch bending is most frequently done with a special hydraulic machine rather than with a die in a press. Hourly production rates are slower for such machines than for presses.

## Bending Calculations

Several formulas are available for computing the forces required for bending. These formulas rely on accurate measurement of the values substituted. Calculations are also necessary for predicting blank dimensions.

**Blank Development.** When metal is bent, the length of the part when measured at the neutral axis is the same as the length of the flat blank. The neutral axis is located midway through the sheet metal thickness from the inside of the bend, which is the compression side.

A common error in determining blank lengths is the failure to add or subtract the sheet metal thickness when necessary. On part prints, the radius at a bend is shown at the inside surface of the bend. Therefore, when radii are on opposite sides, the sheet-metal thickness must often be considered in the calculations.

A general rule in blank development is to first divide the part into straight sections and bends or arcs. Then the length of each section is found. Often, it is necessary to draw in right triangles to connect known to unknown dimensions. Trigonometry is then used to solve for an unknown side or angle. Another rule is that the legs of the triangle should always be drawn parallel to the dimension lines. The hypotenuse then is at the angle of the bend. With this arrangement, the sides of the triangle may be added to or subtracted directly from the dimensions shown on the part print.

**Bottoming Forces.** To overcome springback, the bend area is often placed under high compressive stress to set the metal. This operation is called bottoming and is accomplished by placing a projection or bead on the punch steel. The force for bottoming is difficult to estimate.

Fig. 5 Metal movement during bending

Fig. 6 Changing stress patterns in a bend

Fig. 7 Springback forces

This force will increase due to work hardening of the metal if the yield strength is surpassed. Surpassing of the yield strength is all that is necessary to set the metal. The minimum force for bottoming could be estimated using the sheet metal yield strength. The bottoming force would increase from this minimum value rapidly when press rams were adjusted downward too far.

**Pad Forces.** Bending along a straight line is often performed with a steel punch and an elastomeric (polyurethane) pad. Most production dies of the wiping and channel styles require a pressure plate called a pad to counteract the bending force. In a wiping die with no pad, the sheet-metal blank would simply flip up vertically in the clearance gap, and no bending would occur. The pad acts as a holddown plate in the die. Besides the holddown function, the pad must hold the metal flat against the tip die surface. The

elastomer imposes tensile stresses on the sheet, somewhat as in stretch forming.

A frequent difficulty in bending is that the sheet metal in the area next to the bend tends to rise or lift from the die-steel surface. To simplify the explanation, consider the pad as a knife-edge blade rather than a plate, as shown in Fig. 10. The lifting action is illustrated; the resulting corner condition at the bend is usually called recoil. Under some lighting conditions, a shadow occurs in the depression. A dark line can be seen to follow the bend and may be called a ghost line. On some parts requiring excellent appearance, such shadow lines are not permitted.

Although recoil cannot be prevented entirely, die designers use many methods to control recoil. The recoiling action causes the pad edge to wear rapidly, and hardened inserts are sometimes used in high-volume dies. The pad can be bottomed

against the shoe, but very high tonnages can cause press damage. Bottoming against a lip on the punch steel is more effective and requires less force.

Several comments concerning pads will aid in the design of wiping dies:

- To restrict recoil, the high pad forces are needed just as bending begins. Springs cannot be fully compressed this early, and space is often limited. Most pads must be powered by air or hydraulic cylinders located in the press bed or lower die shoe.
- Recoil problems are more frequent on long bends or flanges. Not only is the pad force high, but the pad must fit tightly for the entire length of bend. Recoil can occur due to the pad surface not being flat.
- It is vital that pads be well guided so that they do not cock or tip due to the unequal loading caused by recoil. An angular pad would permit some recoil despite high pad forces.
- A third function of the pad is to prevent the blank from slipping toward the bending punch. The moving punch causes a dragging action on the blank. High pad forces create enough static friction to prevent blank slippage.

Pad force is one of the largest variables between different companies doing pressworking of sheet metals. The stresses transmitted by frictional forces depend on the surface condition of the blank and the properties of the elastomers. Schey (Ref 1) cites work that indicates higher friction forces reduce springback (Ref 2).

## Bending Operations

Figure 11 illustrates a number of bending terms. The characteristics of bending can be found in many operations for shaping of sheet metal, and each operation has a special name.

Bending in a production plant may be called bending, flanging, hemming, seaming, curling, or corrugating.

**Bending.** Bends are made in sheet metal to obtain rigidity and to obtain a part of desired shape for performance of a certain function. Bending is commonly used to produce structural stampings, such as braces, brackets, supports, hinges, angles, and channels. One troublesome aspect of bending operations arises from the directionality present in rolled steel. Directional lines are set up in the steel in the direction of rolling, causing points of weakness running parallel to the directional lines. Because of these lines, cracking sometimes occurs when metal is bent parallel to the lines. This is especially true of hard-temper metals. To avoid this, bends may be designed across the grain of the metal.

**Flanging** is similar to bending of sheet metal except for one factor: during flanging, the metal bent down is short compared with the overall part size. Most forming operations in automobile production have to do with the formation of flanges. Many straight bending operations are used in making flanges. Where straight flanges are made, the operations are fairly uncomplicated.

**Contour Flanging.** With streamlining and styling of sheet forms, more and more situations

have been created that require curved flanges or contour flange. Although contour flanges usually comprise the sides of a part, they are also used extensively in the formation of flanged holes.

The problems involved in making straight flanges are also common in contour flanging. In addition, contour flanging presents a number of unique problems. These problems arise from the stresses placed on metal in shaping of contours and curves.

Contour flanges are subdivided into three distinct types: stretch flanges, shrink flanges, and reverse flanges.

A stretch flange has a concave curvature. It is called a stretch flange because the material forming the flange must be stretched. This stretching is easily seen in forming of a flange for a hole. The metal used in forming the flange must be elongated.

A shrink flange has a convex curvature. In forming a shrink flange, the metal used to form the flange must be reduced in length. This relationship is easily seen in the flanging of a circular cake pan. The diameter of the finished flange is less than the diameter of the disk from which it was formed.

A reverse flange consists of at least one stretched and one shrunk portion.

Each of these types of flanges creates problems in metal control during forming. To obtain parts conforming to design, special blanks are usually developed. These blanks provide relief for the metal in areas of exceptional strain. In some cases, the flanges are formed in rough blanks and then trimmed.

This is usually done when the stresses involved would result in cracking or severe distortion of developed blanks. Where part design permits, relief of the stresses involved in contour forming is frequently provided by notches or cutouts in the developed blank. These notches provide areas into which the stressed metal may flow and prevent buckling or wrinkling.

As in all stamping operations, the sequence of operations for producing a flanged part is very important. A hole pierced in a part prior to flanging may become distorted during flanging; a flange may interfere with tool access for subsequent operations. Each operation must be sequenced for the most effective production arrangement consistent with quality.

**Hemming and Seaming.** The terms *hemming* and *seaming* are used in a manner similar to their use in the clothing industry. A hem is a fold at the edge of the sheet metal to remove the burred edge and improve the appearance of the edge. The hem also adds slightly to the rigidity of the edge and improves wear resistance. Hems and seams are shown in Fig. 12.

**Curling and wiring** are used to strengthen the edge of sheet metal. Actually, hems, curls, and wiring may be used on flat parts or on round parts such as cams or drums. During wiring, the metal is curled up and over a length of wire. The edge of the sheet metal is strengthened by both the wire and the curl formed in the metal. When the wire is not used, the operation is known as curling or false wiring (Fig. 13).

## Stress-Strain Behavior in Bending\*

### Elastic Bending

Elastic analysis of bending deformation can be performed by simple-beam theory (Ref 3), elasticity solutions, and numerical methods such as the finite-difference and finite-element methods (Ref 4). Generally, numerical methods are suitable for bending of specimens that are subjected to complex loading patterns and that have irregular and/or varying cross-sectional areas. Elasticity solutions are useful when accuracies better than ~5% are desired. Simple-beam theory is used in most testing applications in which plates, strips, bars, and rods are bent in three-point or four-point bending modes. The basic assumptions of the simple-beam theory for pure elastic bending (shear force = 0) are: (a) all sections that are initially plane and perpendicular to the axis of the beam remain plane and

\*Adapted from: P. Dadrás, Stress-Strain Behavior in Bending, *Mechanical Testing and Evaluation*, Vol 8, ASM Handbook, ASM International, 2000, p 109-114

Fig. 11 Bending terms

perpendicular to it after bending; (b) all longitudinal elements (fibers) bend into concentric circular arcs (hence, cylindrical bending); and (c) a one-dimensional stress state is assumed, and the same stress-strain relationship is used for tension and compression.

The first assumption implies a linear distribution for fiber elongations and contractions, as shown in Fig. 3(a). The resulting strain distributions (Fig. 3b, c) are given by (engineering bending strain):

$$\epsilon_x = -\frac{y}{R_n} \quad (\text{Eq 1})$$

and (true bending strain):

$$\epsilon_x = \ln\left(1 - \frac{y}{R_n}\right) \quad (\text{Eq 2})$$

where  $R_n$  is the radius of curvature of the neutral axis. For  $\epsilon_x \leq 0.1$ , the difference between these two strain definitions is  $\leq 5\%$ . Therefore, for most elastic bendings, the engineering strain definition is sufficiently accurate and more convenient. As shown in Fig. 3, the true strain description indicates a nonlinear strain distribution and a maximum compressive strain in the concave inner fiber that is greater than the maximum tensile strain in the outermost fiber.

For a linear elastic material:

$$\epsilon_x = \frac{1}{E}[\sigma_x - \nu(\sigma_y + \sigma_z)] \quad (\text{Eq 3})$$

where  $E$  is the modulus of elasticity for axial loading (Young's modulus), and  $\nu$  is Poisson's ratio. From the third assumption,  $\sigma_y = \sigma_z = 0$ . Therefore:

$$\sigma_x = -E\frac{y}{R_n} \quad (\text{Eq 4})$$

When expressions similar to Eq 3 are written for  $\epsilon_z$  and  $\epsilon_y$ , the following results are obtained:

$$\epsilon_z = \epsilon_y = \nu\frac{y}{R_n} \quad (\text{Eq 5})$$

Also:

$$\epsilon_{xy} = \epsilon_{yz} = \epsilon_{xz} = 0 \quad (\text{Eq 6})$$

Figure 14 illustrates grid deformations in the longitudinal and cross directions. A transverse curvature, called anticlastic curvature (Ref 5), develops with a radius of curvature equal to  $(R_n/\nu)$ . Experimental evidence indicates that the actual radius of anticlastic curvature depends on  $(b^2/2R_nh)$ , where  $b$  is the width, and  $2h$  is the thickness of the beam. For  $(b^2/2R_nh) \leq 1$  (i.e., narrow beams), the  $R_n/\nu$  estimate is sufficiently accurate. For plates and wide beams  $(b^2/2R_nh > 20)$ , the anticlastic deformation is primarily concentrated at the edges.

The location of the neutral axis, which is the line of zero fiber stress in any given section of a member subject to bending, is determined from the condition of zero axial forces acting on the beam. Therefore:

$$\int_A \sigma_x dA = -\frac{E}{R_n} \int_A y dA = 0 \quad (\text{Eq 7})$$

where  $A$  is the cross-sectional area. This equation indicates that the first moment of the cross-sectional area about the neutral axis is zero, which implies that the neutral and the central (centroidal) axes are coincident.

The moment-curvature and moment-stress relationships are found by equating the externally applied bending moment to the internal bending moment at any cross section:

$$M = -\int_A (\sigma_x dA)y \quad (\text{Eq 8})$$

where  $M$  is the bending moment.

For the linear stress distribution shown in Fig. 15, the results are:

$$R_n = \frac{E}{M} I_z \quad \text{and} \quad (\text{Eq 9})$$

$$\sigma_x = -\frac{M_y}{I_z} \quad (\text{Eq 10})$$

where  $I_z$  is the area moment of inertia of the cross section about the  $z$ -axis, which is coincident on the centroidal axis.

The sign (positive or negative) of the bending moment is found from the following relationship: (sign of the bending moment) = (sign of the moment vector)  $\times$  (sign of the outward normal to the section). For example, the bending moment acting on section  $ABCD$  in Fig. 16 is positive, because the moment vector,  $\vec{M}$ , is in the positive  $z$ -direction (right-hand rule), and outward normal of the plane,  $\vec{n}$ , is also in the positive  $x$ -direction.

### Noncylindrical Bending

In the previous section, it was stated that the simple-beam theory considers the effect of bending moments alone (shear force = 0) and assumes a bent configuration consisting of concentric circular arcs (cylindrical bending). For cylindrical bending to occur, these conditions must be met:

- Bending must occur under the action of bending moments alone, which implies zero applied shear force.
- The cross-sectional area of the beam must possess at least one axis of symmetry.
- The vector of the applied bending moment must be in the direction of an axis of symmetry.

For asymmetrical beams such as Z-sections and unequal L-sections, the second and third conditions for cylindrical bending are not satisfied; for unsymmetrical bending of symmetrical beams, the third condition is not met. These cases are significant in structural design and are not considered here. Information on unsymmetrical loading of straight beams can be found in Ref 4.

Fig. 12 Hems and seams

Fig. 13 Wiring and curling

In a majority of testing applications such as three-point bending, roll bending, and press-brake forming, the applied bending moment varies along the length of the specimen. Because shear force  $V = (dM/dx)$ , such variations in the

bending moment imply a nonzero shear force. Therefore, the first condition for cylindrical bending is not met. The resulting shear stress,  $\tau_{xy}$ , which is determined from the equilibrium considerations at a typical section  $m-n$

(Fig. 17a), is:

$$\tau_{xy} = \frac{VQ}{I_z b} \quad (\text{Eq 11})$$

where

$$Q = \int_{A_s} y dA \quad (\text{Eq 12})$$

is the first moment of the shaded area ( $A_s$ ) with respect to the neutral axis (Fig. 17b). The first moment of the unshaded area with respect to the neutral axis gives the same  $Q$ . The distribution of  $\tau_{xy}$  for a rectangular cross section is shown in Fig. 17(c).

Fig. 14 Grid deformations in the longitudinal and cross directions of a beam

Fig. 15 Linear stress distributions in a beam

Fig. 16 Sign convention for bending moment

### Elastic-Plastic Bending

The limit for elastic bending, which is the onset of elastic-plastic bending, is reached when the maximum fiber strain  $(\epsilon_x)_{\max} = (h/R_n)$  becomes equal to  $9(\sigma_y/E)$ , where  $\sigma_y$  is the yield strength, and  $E$  is Young's modulus of the material. For bending beyond this limit, the beam consists of a central elastic core and two plastically deforming zones remote from the neutral axis. For accurate analysis of elastic-plastic bending, factors such as the shift of the neutral axis from the centroidal axis and the effect of radial (transverse) stresses must be considered. Elastic-perfect plastic (Ref 6) and elastic-linear hardening (Ref 7) analyses are available. However, in view of analytical and computational difficulties, an approximate method, which is an extension of the simple-beam theory, is commonly employed. Therefore, the three assumptions stated for elastic bending will be enforced. The location of the neutral axis is assumed to be fixed at the centroidal axis, as it is for elastic bending.

For a beam with the stress-strain curve shown in Fig. 18(a), the development of longitudinal strain and stress at different stages of deformation is shown in Fig. 18(b) and (c), respectively. In Fig. 18(b), a linear strain distribution given by  $\epsilon_x = (-y/R_n)$  was used. When the strain at the

Fig. 17 Distribution of shear stress,  $\tau_{xy}$ , for a rectangular specimen. See text for details.

outermost fiber exceeds 0.1, it is suggested that the true strain distribution (Eq 2) be used. For bending to a radius of curvature equal to  $R_n$ , the strain distribution and the subsequent stress distribution (from the  $\sigma$ - $\epsilon$  curve or from a known constitutive equation for the  $\sigma$ - $\epsilon$  dependence) can be found. The moment,  $M$ , required to produce  $R_n$  is:

$$M = - \int_A (\sigma_x dA) y \quad (\text{Eq 13})$$

The thickness of the elastic core,  $C$  (Fig. 18c), is:

$$C = 2R_n \left( \frac{\sigma_y}{E} \right) \quad (\text{Eq 14})$$

Therefore, in bending plates of the same material to the same radius of curvature  $R_n$ , the fractional thickness of the elastic core  $C/2h$  becomes smaller as the thickness increases.

For elastic-plastic bending, a general equation for the relationship between  $R_n$  and  $M$  (analogous to Eq 9 for the elastic case) does not exist. For the simple case of an elastic-perfect plastic material (Fig. 18d), the following equation is obtained:

$$R_n = \frac{E}{\sigma_y} \left[ 3 \left( \frac{\sigma_y b h^2 - M}{b \sigma_y} \right) \right]^{1/2} \quad (\text{Eq 15})$$

The predictions of this equation at large plastic deformations ( $C/2h \leq 0.02$ ) are not reliable.

### Pure Plastic Bending

The fractional thickness of the elastic core decreases as the ratio  $R_n/2h$  decreases. For  $R_n/2h \leq 10$ , the thickness of the elastic core in a hot rolled strip of AISI 1020 steel is  $\leq 3.2\%$ . In such cases, it is possible to ignore the elastic core altogether and use the analysis for pure plastic bending.

Most plastic bending analyses are for sheet-type specimens in which  $b$  is much greater than  $2h$ . The width strain is small for such a geometry, and plane-strain bending deformation ( $\epsilon_z = 0$ ) is commonly assumed. Also, the first two assumptions of the simple-beam theory are still applied. However, the radial (transverse) stresses and

strains induced by higher curvatures are considered, and a plane-in state, rather than a one-dimensional stress state (the third assumption of the simple-beam theory), is assumed. Also, the neutral axis is not fixed at the centroid, and thickness variations due to bending sometimes are incorporated into the solution. Figure 19 shows the geometry of deformation and the strain and stress states at different zones.

At the onset of the assumed full plastic condition,  $R_c = R_n = R_u$ . In the current state, the fiber with radius of curvature equal to  $R_n$  is being overtaken by the neutral axis and is experiencing unloading from a compressive tangential stress field. Accordingly, all fibers below the neutral axis  $r \leq R_n$  have been progressively compressed, while those situated above  $R_c$  have been consistently stretched during deformation. All fibers in the interval  $R_n \leq r < R_c$  have been overtaken by the neutral axis. Fibers between  $R_u < r < R_c$  have now been stretched beyond their original length due to reverse loading, while those located in  $R_n \leq r \leq R_u$  have yet to recover their original undeformed length.

As expected, a comprehensive analysis accounting for the described fiber movements is very complicated (Ref 8). A compromise solution (Ref 9), which ignores thickness variations and assumes rigid-perfect plastic material behavior, provides useful approximations for the stress-strain distributions in plastic bending.

When a rigid-perfect plastic material model is used (Fig. 19c), the same stress-strain relationship applies to all fibers with  $r \geq R_n$ . As a result, the distinction among  $R_n$ ,  $R_u$ , and  $R_c$  becomes inconsequential. This eliminates the complicated task of describing the behavior of fibers in reversed loading and the Bauschinger effect.

The state of stress acting on a typical element is shown in Fig. 20, where  $\sigma_\theta$  is the circumferential (tangential) stress, and  $\sigma_r$  is the radial (transverse) stress. The equilibrium equation for plane-strain deformation is:

$$\frac{d\sigma_r}{dr} = \frac{\sigma_\theta - \sigma_r}{r} \quad (\text{Eq 16})$$

The effective or significant stress,  $\bar{\sigma}$ , and strain,  $\bar{\epsilon}$ , for plane-strain deformation, using von Mises criterion, are, respectively:

$$\bar{\sigma} = \pm \frac{\sqrt{3}}{2} (\sigma_\theta - \sigma_r) \quad (+) \text{ for } R_o \geq r \geq R_n \\ (-) \text{ for } R_n > r > R_i \quad (\text{Eq 17})$$

and

$$\bar{\epsilon} = \frac{2}{\sqrt{3}} |\epsilon_\theta| \quad (\text{Eq 18})$$

where  $\epsilon_\theta = \ln r/R_n$ . Substituting  $(\sigma_\theta - \sigma_r)$  from Eq 16 into Eq 15 and putting  $\sigma_r = 0$  at  $r = R_o$  and  $r = R_i$ , these equations for the distribution of  $\sigma_r$  are obtained:

$$\sigma_r = - \left( \frac{2\bar{\sigma}}{\sqrt{3}} \right) \ln \left( \frac{R_o}{r} \right) \text{ for } R_n \leq r \leq R_o \quad (\text{Eq 19})$$

$$\sigma_r = - \left( \frac{2\bar{\sigma}}{\sqrt{3}} \right) \ln \left( \frac{r}{R_i} \right) \text{ for } R_i \leq r \leq R_n \quad (\text{Eq 20})$$

From the expressions for  $\sigma_r$  and Eq 16, the following expressions for  $\sigma_\theta$  are determined:

$$\sigma_\theta = - \left( \frac{2\bar{\sigma}}{\sqrt{3}} \right) \left[ 1 - \ln \left( \frac{R_o}{r} \right) \right] \text{ for } R_n \leq r \leq R_o \quad (\text{Eq 21})$$

$$\sigma_\theta = - \left( \frac{2\bar{\sigma}}{\sqrt{3}} \right) \left[ 1 + \ln \left( \frac{r}{R_i} \right) \right] \text{ for } R_i \leq r \leq R_n \quad (\text{Eq 22})$$

Because of equilibrium considerations, the radial stress must be continuous at  $r = R_n$ . Applying this condition to Eq 19 and 20, the location of the neutral axis can be found:

$$R_n = \sqrt{R_i R_o} \quad (\text{Eq 23})$$

Figure 21 is a schematic of the distributions of  $\sigma_r$  and  $\sigma_\theta$ . In the figure,  $\sigma_r$  is continuous and compressive throughout the plate thickness, while  $\sigma_\theta$  changes from tension to compression at the neutral axis. The bending moment, which according to this solution is independent of  $R_n$ , becomes:

$$M = \int_{R_i}^{R_o} (\sigma_\theta b dr) r = \left( \frac{2}{\sqrt{3}} \right) \bar{\sigma} b h^2 \quad (\text{Eq 24})$$

where  $h$  is half-thickness, and  $b$  is the plate width.

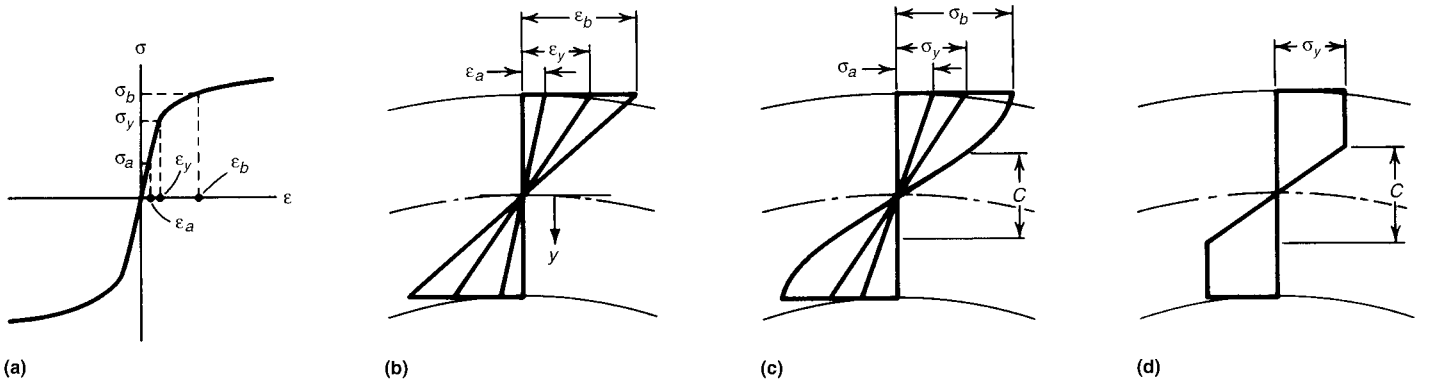

Fig. 18 Stress-strain distributions in a beam. (a) Stress-strain curve. (b) Strain distribution. (c) Stress distribution. (d) Stress distribution for elastic-perfect plastic material

The maximum radial stress occurs at the neutral axis. Its magnitude from Eq 19 and 23 is:

$$(\sigma_r)_{\max} = - \left( \frac{\bar{\sigma}}{\sqrt{3}} \right) \ln \left( \frac{R_o}{R_i} \right) \tag{Eq 25}$$

The ratio between  $(\sigma_r)_{\max}$  and the tangential stress at  $r = R_o$  for four plates of different thicknesses, all bent to an inside radius of  $R_i = 25 \text{ mm}$  (1 in.), is given in Table 1. This table shows that for plastic bending to

$(R_n/2h) > 10$ , the magnitude of  $(\sigma_r)_{\max}$  becomes very small. In such cases, the effect of  $\sigma_r$  can be neglected in the analysis, and the elastic-plastic bending solution based on the simple-beam theory can be used.

**Fig. 19** Pure plastic bending of strip specimen. **Fig. 21** Schematic of circumferential,  $\sigma_\theta$ , and radial,  $\sigma_r$ , stresses in a plate during bending. Source: Ref 9

More elaborate analyses of plastic bending (Ref 8, 10) commonly involve complicated numerical computations. Hence, no equations can be given. A comparison between the results of the analysis in Ref 9 and a solution for rigid work-hardening material behavior (Ref 8) is shown in Fig. 22. In this case, the result from Ref 8 is for a model material with a high rate of

strain hardening:

$$\bar{\sigma} = 70 + 300\bar{\epsilon}^{0.5} \text{ MPa} \quad (\text{Eq 26})$$

In using the analysis from Ref 8,  $\bar{\sigma} = 120 \text{ MPa}$  (17.4 ksi), which is the approximate average flow stress for bending to  $\bar{\epsilon} = 0.11$ , and  $\bar{\sigma} = 169.5 \text{ MPa}$  (24.6 ksi), as shown in Fig. 22(b), have been assumed. As expected, some differences in the predicted stress distributions are observed.

However, by using  $\bar{\sigma} = 169.5 \text{ MPa}$  (24.6 ksi) in the solution from Ref 8, a close agreement (percent different <6) between the estimates for the fiber stresses at  $r = R_i$  and  $r = R_o$  is obtained. Because the prediction of maximum fiber stress and strain is of special interest, the following procedure based on the solution in Ref 8 is suggested. First, find the maximum fiber strain:

$$\epsilon_o = -\epsilon_i = \ln \sqrt{\frac{R_o}{R_i}} \quad (\text{Eq 27})$$

where  $\epsilon_o$  and  $\epsilon_i$  represent the maximum fiber strain at the outer and inner radii, respectively. Using the stress-strain equation or stress-strain curve for the material, determine  $\bar{\sigma}$  as the flow stress at  $\epsilon_o$ . The maximum fiber stress is  $2\bar{\sigma}/\sqrt{3}$ .

### Residual Stress and Springback

When a specimen that has been bent beyond the elastic limit is unloaded, the applied moment  $M$  becomes zero, and the radius of curvature increases from  $R_n$  to  $R'_n$ . For a fiber at distance  $y$  from the neutral axis, this produces a strain difference:

$$\Delta\epsilon_x = y \left( \frac{1}{R_n} - \frac{1}{R'_n} \right) \quad (\text{Eq 28})$$

The removal of the bending moment, which is an unloading event, is assumed to be elastic. Therefore:

$$\Delta\sigma_x = E\Delta\epsilon_x = Ey \left( \frac{1}{R_n} - \frac{1}{R'_n} \right) \quad (\text{Eq 29})$$

The change in bending moment for complete unloading is  $\Delta M = M$ , where  $M$  is the applied bending moment prior to unloading. Therefore:

$$\int_A \left[ Ey \left( \frac{1}{R_n} - \frac{1}{R'_n} \right) dA \right] y = - \int_A (\sigma_x dA) y \quad (\text{Eq 30})$$

which reduces to:

$$\frac{1}{R_n} - \frac{1}{R'_n} = - \frac{\int_A \sigma_x y dA}{EI_z} \quad (\text{Eq 31})$$

The distribution of the residual stresses can be found from either of the following equations:

$$\sigma'_x = \sigma_x + \Delta\sigma_x = \sigma_x - \left( \frac{y}{I_z} \right) \int_A \sigma_x y dA \quad (\text{Eq 32})$$

$$\sigma'_x = \sigma_x + yE \left( \frac{1}{R_n} - \frac{1}{R'_n} \right) \quad (\text{Eq 32a})$$

It is important that the correct signs for  $\sigma_x$  and  $y$  be used when applying these equations.

As an example, the springback and the residual-stress distribution of a strip of annealed 1095 steel was examined (Ref 11). For this material, yield strength is  $\sigma_y = 308 \text{ MPa}$  (44.7 ksi), Poisson's ratio is  $\nu = 0.28$ , and the approximate constitutive equation for  $\sigma$  in metric units of measure is:

$$\bar{\sigma} = (2 \times 10^5 \text{ MPa}) \epsilon \quad \text{for } \epsilon \leq 0.00154 \quad (\text{Eq 33})$$

$$\bar{\sigma} = (896 \text{ MPa}) \epsilon^{0.16} \quad \text{for } \epsilon \geq 0.00154 \quad (\text{Eq 34})$$

In English units of measure,  $\sigma$  is:

$$\bar{\sigma} = (29 \times 10^6 \text{ psi}) \epsilon \quad \text{for } \epsilon \leq 0.00154$$

$$\bar{\sigma} = (126 \text{ ksi}) \epsilon^{0.16} \quad \text{for } \epsilon \geq 0.00154$$

The width of the strip,  $b$ , is 50 mm (2 in.), and its thickness,  $2h$ , is 5 mm (0.2 in.). It is assumed that the strip is bent to  $R_n = 100 \text{ mm}$  (4 in.). Because  $(b/2h) = 10$ , plane-strain deformation prevails. Because of this, the elastic modulus in plane-strain:

$$E' = \frac{E}{1 - \nu^2} \quad (\text{Eq 35})$$

is employed, and the plastic flow stresses (Eq 34) are multiplied by  $(2/\sqrt{3})$ . These approximate plane-strain adjustments are considered adequate when the simplified elastic-plastic analysis, which was discussed earlier in this article, is used. The thickness of the elastic core in metric units of measure is:

$$C = \frac{2R_n\sigma_y}{E'} = 2(100) \frac{(2 \times 308)/\sqrt{3}}{2.17 \times 10^5} \quad (\text{Eq 36})$$

$$C = 0.33 \text{ mm}$$

In English units of measure, the thickness of the elastic core is:

$$C = \frac{2R_n\sigma_y}{E'} = \frac{2(3.937) \left( 2 \times \frac{44.7}{\sqrt{3}} \right)}{(31,465)}$$

$$C = 0.013 \text{ in.}$$

which is 6.6% of the total plate thickness. The final radius of curvature in metric units of measure after springback is found from Eq 31:

$$\frac{1}{100} - \frac{1}{R'_n} = - \frac{2}{EI_z} \times \left[ \int_0^{C/2} -2.17 \times 10^5 \left( \frac{y}{100} \right) b dy + \int_{C/2}^h - \left( \frac{2}{\sqrt{3}} \right) 869 \left( \frac{y}{100} \right)^{0.16} by dy \right] \quad (\text{Eq 37})$$

**Table 1** Ratio between maximum radial stress and tangential stress for plate of various thicknesses

(b)

**Fig. 22** Comparison of results for determining plastic bending in a plate. (a) Distribution of tangential and radial stresses for a 25 mm (1 in.) thick plate bent to  $R_i = 100 \text{ mm}$  (4 in.). (b) Stress-strain diagrams used in the analyses for (a)

which results in  $R'_n = 116.9$  mm (4.60 in.). A more elaborate analysis of springback (Ref 11) for this case predicts  $R'_n/2h = 23.41$  (or  $R'_n = 117.05$  mm, or 4.608 in.). Also, for bending the same strip to  $R_n = 40$  mm (1.6 in.) and  $R_n = 500$  mm (19.7 in.), the final radii of curvature from Eq 31 are 42.8 mm (1.68 in.) and 1150 mm (45.3 in.), respectively. The corresponding results from Ref 11 are 42.9 mm (1.69 in.) and 1075 mm (42.3 in.).

The distribution of residual stresses after bending to  $R_n = 100$  mm (3.937 in.) is obtained from Eq 32(a). Therefore, in this case, in metric units:

$$\sigma'_x = \sigma_x + yE(0.0014457) \quad (\text{Eq 38})$$

In English units:

$$\sigma'_x = \sigma_x + yE(0.03672)$$

At  $R = R_i$ ,  $y = h = 2.5$  mm (0.098 in.):

$$\epsilon_x = -0.025$$

and

$$\sigma_x = -\left(\frac{2}{\sqrt{3}}\right)(869)(0.025)^{0.16} = -556 \text{ MPa}$$

or

$$\sigma_x = -\left(\frac{2}{\sqrt{3}}\right)(126)(0.025)^{0.16} = -80.63 \text{ ksi}$$

For this location:

$$\begin{aligned} \sigma'_x &= -556 + 2.5(2.17 \times 10^5) \times (0.0014457) \\ &= +228 \text{ MPa} \end{aligned}$$

or

$$\begin{aligned} \sigma'_x &= -80.63 + 0.098(31,465)(0.03672) \\ &= +32.6 \text{ ksi} \end{aligned}$$

Similarly, the magnitude of  $\sigma_x$  for other values of  $y$  can be determined. Figure 23 shows the distribution of applied and residual stresses.

## Bendability

Bendability is the ability of a material to be bent around a specified radius without fracture. It is typically expressed as the minimum bending radius without fracture when bent along a

Fig. 23 Distribution of applied and residual stresses

straight line. Sheet metal bendability is a critical factor in many forming operations, and the evaluation of bendability has been addressed in various publications (Ref 12–19). The analytical methods in Ref 12–17 are based on elementary bending theory with the assumption of small curvature bending. In Ref 18, however, an analysis is developed for sheet metal of work hardening materials that are subjected to large curvature plane-strain bending. Bendability criteria for large-curvature bending are suggested in Ref 18.

If small-curvature bending is assumed, two bend-ductility equations can be used to derive minimum bend radii from tensile-test elongation or reduction of area (Ref 13). The derivation of the two relevant bend-ductility equations from Ref 13 (adapted here) assumes the following:

- The fracture strain at the outer fiber of a bending specimen equals the fracture strain on a tensile specimen.
- The materials are homogeneous and isotropic.
- The form (sheet, plate, or bar) bends in plane strain.

To correlate minimum bend radius with reduction in area, it is assumed that the maximum true strain that a tensile specimen can endure is the true strain ( $\epsilon_f$ ) in the reduced section at the instant of fracture.

$$\text{Then: } \epsilon_f = \ln \frac{A_0}{A_f} = \frac{w_0 t_0}{w_f t_f}$$

Where,  $w_0$  and  $t_0$  are width and thickness of untested specimen;  $w_f$  and  $t_f$  are width and thickness of specimen after fracture;  $A_0$  is sectional area of a specimen before test; and  $A_f$  is sectional area of a specimen after fracture. By definition, percentage of reduction in area is,

$$(A_r) = \frac{A_0 - A_f}{A_0} \times 100$$

Combining these two equations, we get:

$$\epsilon_f = \ln \left( \frac{100}{100 - A_r} \right)$$

With reference to the illustrated bending specimen (Fig. 24), the outside fiber is strained in tension; the inside in compression.  $l_f$  is length of outside surface;  $l_0$  is length of  $l_f$  at the neutral

Fig. 24 Illustration of bend-specimen variables

axis;  $\theta$  is angle of bend; and  $t$  is thickness. Assume that the neutral axis of bending lies in the midfiber. Taking the inner bending radius ( $R$ ) of the beam into consideration, the arc length along the neutral axis subtended by the angle  $\theta$  is  $(R + \frac{t}{2}) \theta$ , and the arc length of the outside fiber is  $(R + t) \theta$ . Therefore, the true strain in the outside fiber ( $\epsilon_0$ ) is given by:

$$\epsilon_0 = \ln \left( \frac{l_f}{l_0} \right) = \ln \left[ \frac{(R+t) \theta}{\left(R + \frac{t}{2}\right) \theta} \right] = \ln \left[ \frac{R+t}{R + \frac{t}{2}} \right]$$

Equating the last two equations gives the following:

$$\frac{100}{100 - A_r} = \frac{R+t}{R + \frac{t}{2}} \quad \text{or:}$$

$$\frac{R}{t} = \frac{50}{A_r} - 1 \quad (\text{see Fig. 25}).$$

To correlate minimum bend radius with elongation, we start with the percentage elongation ( $e_1$ ) of a tensile specimen. By definition,

$$e_1 = \frac{l_f - l_0}{l_0} \times 100 = \left( \frac{l_f}{l_0} - 1 \right) \cdot 100$$

Here,  $l_f$  is gage length of a tensile specimen after fracture, and  $l_0$  is initial gage length.  $\epsilon_f$  is fracture strain in tension test, as before. Thus  $\epsilon_f = \ln \frac{l_f}{l_0}$ . From the first equation  $\frac{e_1}{100} = \frac{l_f}{l_0} - 1$ . Substituting this equation into the previous one, we get:

$$\epsilon_f = \ln \left( \frac{e_1}{100} + 1 \right)$$

Equating  $\epsilon_f$  to  $\epsilon_0$ , we arrive at:

$$\frac{e_1}{100} + 1 = \frac{R+t}{R + \frac{t}{2}}$$

By simplification, the following equations result:

$$\begin{aligned} \frac{e_1}{100} \left( R + \frac{t}{2} \right) + R + \frac{t}{2} &= R + t, \\ \text{or } \frac{e_1}{100} \left( R + \frac{t}{2} \right) &= \frac{t}{2} \end{aligned}$$

Dividing by  $t$ , one has:

$$\begin{aligned} \frac{e_1}{100} \left( \frac{R}{t} + \frac{1}{2} \right) &= \frac{1}{2} \\ \text{or } \frac{R}{t} + \frac{1}{2} &= \frac{50}{e_1} \end{aligned}$$

Rearranging gives:

$$\frac{R}{t} = \frac{50}{e_1} - \frac{1}{2} \quad (\text{see Fig. 26}).$$

Testing of this analytical approach was evaluated by comparison with two types of bend tests (Ref 2). Figures 25 and 26 show that experimental data points fall along the theoretical curves. Thus, there is a definite relation between the  $\frac{R}{t}$  ratio and the ductility, as given by reduction in area or elongation. The two equations can indicate minimum bend radii with respect to a particular thickness. Because handbooks usually give elongation and reduction

**Fig. 25** Comparison of bending limit with tensile-test reduction in area. By knowing the reduction in area and thickness ( $t$ ) of a material in a given form, one can calculate the minimum bend radius ( $R$ ) that a sheet, plate, or bar will withstand on being formed. Experimental data points for several materials with varying thicknesses fall on or close to the line calculated with a formula relating to three factors. Initials CR and CW stand for "cold rolled" and "cold worked." Alloy RC 130 B consists of titanium plus 3.5 Mn and 3.0 Al. Source: Ref 13 and 19

in area values, the equations can be useful in approximating minimum bend radii for small-curvature bends. See also the article "Forming of Carbon Steels" for more information on minimum bend Radii.

# Press-Brake Forming

**PRESS-BRAKE FORMING** is a process in which the workpiece is placed over an open die and pressed down into the die by a punch that is actuated by the ram portion of a machine called a press brake. The process is most widely used for the forming of relatively long, narrow parts that are not adaptable to press forming and for applications in which production quantities are too small to warrant the tooling cost for contour roll forming.

Simple V-bends or more intricate shapes can be formed in a press brake. Operations such as blanking, piercing, lancing, shearing, straightening, embossing, beading, wiring, flattening, corrugating, and flanging can also be carried out in a press brake. Information on press-brake forming can also be found in the articles "Press Brakes," "Forming of Carbon Steels," "Press Forming of Coated Steel," "Contour Roll Forming," "Forming of Stainless Steel," and "Forming of Aluminum Alloys" in this Volume.

## Principles

In press-brake forming, as in other forming processes, when a bend is made, the metal on the inside of the bend is compressed or shrunk, and that on the outside of the bend is stretched. The applied forces create a strain gradient across the thickness of the work metal in the area of die contact. Tensile strain occurs in the outer fiber, and compressive strain in the inner fiber; both decrease in magnitude toward the neutral axis.

The setup and tooling for press-brake forming are relatively simple (Fig. 1). The distance the punch enters the die determines the bend angle and is controlled by the shut height of the machine. The span width of the die, or the width of the die opening, affects the force needed to bend the workpiece. The minimum width is determined by the thickness of the work and sometimes by the punch-nose radius. After the tools have been set up and the shut height has been adjusted, the press brake is cycled, and the work metal is bent to the desired angle around the nose radius of the punch.

## Applicability

Press-brake forming is most widely used for producing shapes from ferrous and nonferrous

metal sheet and plate. Although sheet or plate 6.4 mm (0.250 in.) thick or less is most commonly formed in a press brake, metals up to 25 mm (1 in.) thick have often been used, as in the following example.

**Example 1: Bending 25 mm (1 in.) Thick Steel Plate.** A 280 mm (11 in.) long bend was made in a 25 mm (1 in.) thick low-carbon steel plate in a 2700 kN (300 tonf) press brake to make the part shown in Fig. 2. The bend radius was 51 mm (2 in.); the included angle was 130°. The plate was air bent in a V-die with a punch that was made from a steel tube 102 mm (4 in.) in diameter.

After bending, the edges of the part were machined parallel, as shown in Fig. 2. The workpiece became part of a welded assembly—a frame brace on an industrial lift truck.

**Workpiece Dimensions.** The length of plate or sheet that can be bent is limited only by the size of the press brake. For example, a 5350 kN (600 tonf) press brake can bend a 3 m (10 ft) length of 19 mm (3/4 in.) thick low-carbon steel plate to a 90° angle, with an inside radius of the bend equal to stock thickness. If the included angle of the bend is greater than 90°, if the bend radius is larger than stock thickness, or if the length of bend is less than the bed length, a press of correspondingly lower capacity can be used.

Forming can be done at room or elevated temperature. For elevated-temperature forming in which the punch bottoms, the punch and die should be heated as well as the blank. In air bending, the blank is heated, and the punch is sometimes heated, depending on the area of contact between punch and blank and the metal thickness.

**Fig. 1** Typical setup for press-brake forming in a die with a vertical opening.  $R$ , punch radius;  $r$ , die radius;  $s$ , span width;  $t$ , metal thickness

**Work Metals.** Press-brake forming is applicable to any metal that can be formed by other methods, such as press forming and roll forming. Low-carbon steels, high-strength low-alloy steels, stainless steels, aluminum alloys, and copper alloys are commonly formed in press brakes. High-carbon steels and titanium alloys are less frequently formed in a press brake, because they are more difficult to form.

The formability of all metals decreases as the yield strength increases. Therefore, in press-brake forming, power requirements and spring-back problems increase and the degree of bending that is practical decreases as the yield strength of the work metal increases.

## Press Brakes

The primary advantages of press brakes are versatility, the ease and speed with which they can be changed over to a new setup, and low tooling costs. A press brake is basically a slow-speed punch press that has a long, relatively narrow bed and a ram mounted between end housings (Fig. 3). Rams are actuated mechanically or hydraulically. Additional information on press brakes is provided in the article "Press Brakes" in this Volume.

**Mechanical Press Brakes.** The ram of a mechanical press brake is actuated by a crank or an eccentric through a gear train in which there is a clutch and a flywheel. The gear train is usually designed to provide fast movement of the ram. Shut height (the distance between ram and bed at the bottom of the stroke) is adjustable by means of a screw (usually powered) in the pitman, or

**Fig. 2** Frame brace that was air bent from thick plate in a V-die in a 2700 kN (300 tonf) press brake. Dimensions given in inches

link, at each end of the ram. The length of the ram stroke, however, is constant.

One advantage of a mechanical press brake over a hydraulic press brake is that the mechanical type can develop greater-than-rated tonnage, because of the inertia of the flywheel moving the ram and the mechanical advantage of the crank near the bottom of the stroke. As a result, most mechanical press brakes have extra-strong frames to allow for occasional overloading. However, overloading should not be encouraged, because serious damage to the press brake may occur from improper setup. Another advantage is that operating speeds are greater in mechanical press brakes than in hydraulic press brakes. The greater speed is especially useful for long-run production of workpieces that are easily handled. Greater speed also permits instantaneous, high impact forces when the punch contacts the work metal. This impact force is useful in some operations, although it can damage the machine if the setup lacks rigidity.

A disadvantage of a mechanical press brake is that the stroke cannot be adjusted or controlled to the same degree as is possible with the hydraulic type. However, mechanical press brakes are available at additional cost with devices that permit a rapid advance to work and then a slower speed during forming.

**Hydraulic Press Brakes.** The ram of a hydraulic press brake is actuated by two double-acting cylinders, one at each end of the ram. Force supplied by the hydraulic mechanism will not exceed the press rating; therefore, it is almost impossible to overload a hydraulic press brake. (When thicker metal is inadvertently used, the ram stalls.) Therefore, frames can be lighter and less costly than those for mechanical press brakes, which are subject to overloading.

In hydraulic press brakes, length of stroke and location of the top and bottom of the stroke (within limits of the cylinder length) are adjustable. The point of rapid advance and return of

the ram and its speed during contact with the workpiece are also adjustable; this adjustment makes possible a dwell period, which is often helpful in controlling springback. Cycles established by means of the various adjustments are reproduced by switches in the control circuit.

Even though devices are available that permit some control of the stroke of a mechanical press brake, the degree of control that is possible for a hydraulic press brake is considerably greater. For example, the ram on a hydraulic press brake can be reversed or its speed can be changed at any point on the stroke. Because of these features, a hydraulic press brake is often preferred for the segmental forming of stock longer than the dies, for the forming of large sheets that would be likely to whip in a mechanical press brake, and for the forming of difficult-to-form metals.

**Hybrid press brakes** incorporate both mechanical and hydraulic elements in the ram drive. The hydraulic-mechanical hybrid consists of a mechanical press brake driven by a rotary hydraulic motor. Containing a vane that rotates 270° between stops, the rotary hydraulic motor has replaced the piston used in a hydraulic cylinder. As it moves between the two stops, the motor propels the eccentric shaft through one complete cycle, driving the ram to the stroke bottom and back to the top.

The hybrid press brake combines the best features of both mechanical and hydraulic press brakes. It offers the same accuracy and operating speeds obtainable with the mechanical press brake while providing the adjustable length and controllability of the hydraulic press brake.

## Selection of Machine

A mechanical press brake is usually preferred for quantity production because its speed is greater than that of a hydraulic press brake.

Fig. 3 Principal components of a mechanical press brake

Conversely, a hydraulic press brake is generally preferred for varied short-run production because it is more versatile.

Apart from the method of actuating the ram, major factors that must be considered in the selection of a press brake for a given application are the size, length of stroke, and tonnage capacity of the press brake. Table 1 lists capacities and other details for mechanical and hydraulic press brakes.

**Size** is determined by length of bed and length of stroke (maximum stroke, in a hydraulic press brake). The bed length must be able to accommodate the longest bend required. Bed length can also be dictated by the need to mount more than one die in the press to permit a sequence of related operations in the machine at the same time. Under these conditions, it may be necessary to shim the dies so that the punches will bottom simultaneously. For example, if the parts are 305 mm (12 in.) long and six dies are required, the parts could be mounted on a press brake with a bed length of 1.8 m (72 in.) plus allowance for space between dies.

Standard press brakes are available with a maximum bed length of 7.3 m (24 ft). Still larger press brakes are available on special order. The longer the bed, however, the more massive it must be to provide enough rigidity for holding product dimensions, until a length is finally reached at which cost is prohibitive. Similarly, for a given capacity, the maximum stock thickness that can be accommodated decreases as bed length increases.

**Length of stroke** is an important consideration in any operation in which the height of the sides of the member after bending (such as a deep channel or box) causes interference between the top edge of the formed section and the ram. In addition, the greater the leg height after forming, the longer the stroke must be to allow the finished part to be withdrawn (unless it can be withdrawn from the end, under which conditions length of stroke is not important). Press brakes having a stroke length as great as 152 mm (6 in.) (mechanical) and 457 mm (18 in.) (hydraulic) are available as standard equipment. Modifications for providing increased stroke length are available at extra cost.

**Capacity** is stated in tons of force developed by the ram at the midpoint of the stroke. Capacities of commercial press brakes range from 70 kN to 22 MN (8 to 2500 tonf). Required capacity is governed by the size and bending characteristics of the work metal and by the type of bend to be made. A formula for determining the capacity required for 90° bends using V-dies without bottoming is:

$$L = \frac{lt^2kS}{s} \quad (\text{Eq 1})$$

where  $L$  is press load (in tonf),  $l$  is length of bend (parallel to bend axis) (in inches),  $t$  is work metal thickness (in inches),  $k$  is a die-opening factor (varying from 1.2 for a die opening of  $16t$  to 1.33 for a die opening of  $8t$ ),  $S$  is tensile strength of the

**Table 1** Capacities, sizes, speeds, and ratings for mechanical and hydraulic press brakes

(a) Normal press speed gives rated capacity. High press speeds, m/min (in./min), together with press tonnage ratings, are as follows: (b) 1.4 and 1.7 m/min (57 and 65 in./min) at 620 kN (70 tonf); (c) 1.1 and 1.6 m/min (44 and 62 in./min) at 1070 kN (120 tonf); (d) 1.3 and 1.6 m/min (51 and 62 in./min) at 1420 kN (160 tonf); (e) 1.4 and 1.5 m/min (54 and 58 in./min) at 1780 kN (200 tonf); (f) 1.4 and 1.3 m/min (56 and 51 in./min) at 2140 kN (240 tonf); (g) 1.2 and 1.2 m/min (48 and 47 in./min) at 2670 kN (300 tonf); (h) 1.5 and 1.1 m/min (58 and 44 in./min) at 3560 kN (400 tonf)

work metal (in tons per square inch), and  $s$  is width of die opening (in inches) (Fig. 1).

**Sample Calculation.** Assume a constant of 1.33, a V-die opening of  $8t$ , and a bend 305 mm (12 in.) long made in 6.35 mm (0.250 in.) thick plate having a tensile strength of 30 tsi. Substituting these numerical values in Eq 1 yields:

$$L = \frac{12 \cdot 0.250^2 \cdot 1.33 \cdot 30}{2} \quad (\text{Eq 2})$$

or approximately a 130 kN (15 tonf) capacity requirement for this 90° bend.

For simple bending, the force required increases proportionately with the length of the workpiece or with the square of the work metal thickness. For example, in Eq 2, if the workpiece were 1220 mm (48 in.) long, a 530 kN (60 tonf) capacity would be needed. For producing offset bends (Fig. 4b), approximately four times as much pressure is required as for simple V-bends.

## Dies and Punches

V-bending dies and their corresponding punches (Fig. 4a and d) are the tools most commonly used in press-brake forming. The width of the die opening ( $s$ , Fig. 4a) is usually a minimum of  $8t$  (eight times the thickness of the work metal).

The nose radius of the punch should not be less than  $1t$  for bending low-carbon steel, and it must be increased as the formability of the work metal decreases. The radius of the V-bending die must be greater than the nose radius of the punch by an

**Fig. 4** Dies and punches most commonly used in press-brake forming. (a) 90° V-bending. (b) Offset bending. (c) Radiused 90° bending. (d) Acute-angle bending. (e) Flattening for three types of hems. (f) Combination bending and flattening. (g) Gooseneck punch for multiple bends. (h) Special clearance punch for multiple bends

amount equal to or somewhat greater than the stock thickness in order to allow the punch to bottom. Optimal dimensional control is obtained by bottoming the punch to set the bend.

When producing 90° bends in a bottoming die, the V-die is ordinarily provided with an included

angle of 85 to 87°. Several trials are often necessary, and various adjustments must be made on the punch setting before the required 90° bend can be obtained.

**Offset Dies.** Punch and die combinations such as the one shown in Fig. 4(b) are often used

to produce offset bends. Because an offset bend requires approximately four times as much force as a 90° V-bend, offset bending is usually restricted to relatively light-gage metal (3.2 mm, or 0.125 in., or less). The depth of offset ( $h$ , Fig. 4b) should be a minimum of six times the work metal thickness to provide stability at the bends.

**Radius forming** is done with a 90° die and a punch, each having a large radius (Fig. 4c). When the punch is at the bottom position, the inside radius of bend in the workpiece conforms to the radius of the punch over a part of the curve. The harder the punch bottoms, the more closely the work metal wraps around the punch nose, resulting in a smaller radius of bend and less springback. Uniformity of bend angle depends greatly on the uniformity of the work metal thickness.

**Acute angles** are formed by the die and punch shown in Fig. 4(d). The air-bending technique (see the section "Air Bending" in this article) is often used to produce acute angles. Acute angles are formed as the first step in

making a hem. For this purpose, the die is often bottomed to make the bend angle as acute as possible. A disadvantage of bottoming is that the metal becomes work hardened, so that the hem is likely to crack when formed.

**Flattening dies**, shown in Fig. 4(e), are used to produce three types of hems (also shown in Fig. 4e) after the metal has been formed into an acute angle. The combination die shown in Fig. 4(f) produces an acute angle on one workpiece and a hem on another, so that a piece is started and a piece completed with each stroke of the press brake.

**Gooseneck punches** (Fig. 4g) and narrow-body, or special clearance, punches (Fig. 4h) are used to form workpieces to shapes that prevent the use of punches having conventional width (two such workpiece shapes are also shown in Fig. 4g and h).

**Tongue Design.** The punches shown in Fig. 4 as well as in several other illustrations in this article are provided with a simple, straight tongue for securing the punch to the ram. Although this design of tongue is generally accepted, in

some shops punches with a hook type of tongue (see Fig. 9, and the punch for operation 4 in Fig. 21) are used exclusively as a safety precaution. A punch mounted with a hooked tongue cannot fall out. In one shop, it was estimated that hooked tongues increased punch cost by approximately 10% over the cost of straight-tongue punches.

**Wiping Dies.** Another type of bending die is a wiping die (Fig. 5). A pressure pad that is either spring loaded or attached to a fluid cylinder clamps the workpiece to the die before the punch makes contact. The punch descends and wipes one side of the workpiece over the edge of the die. The bend radius is on the edge of the die. To prevent the wiping action from being too severe, there may be a radius or chamfer on the mating face of the punch. When springback must be compensated for, the die is undercut to permit overbending. The flange metal can be put in slight tension by ironing it between the punch and the die. Sharp bends generally cannot be made in one operation in a wiping die without cracking the metal, because a punch or die with a sharp edge will cut the metal rather than bend it.

## Special Dies and Punches

Dies that combine two or more operations to increase productivity in press-brake forming are generally more complicated and costly than those illustrated in Fig. 4. Before special dies are designed for a specific application, the increased tooling cost must be balanced against decreased time on the press brake. Generally, the quantity of identical parts to be produced is the major factor in selecting special dies.

**Channel Dies.** A channel die (Fig. 6a) can form a channel in one stroke of the press brake, while two strokes would be required using a conventional V-die. Because it is necessary to have an ejector in the die to extract the workpiece, channel dies cost more than conventional dies. This higher cost can be justified only on the basis of large-quantity production. It is ordinarily not necessary to have a stripper on the punch, because springback usually causes the part to release. The ejector in the die may be of the spring, hydraulic, or air-return type. The stripper for the punch (if needed) is a release-wedge device or a knockout piece. The use of a channel die, regardless of production quantities, is limited by work metal thickness, corner radii, and required flatness of the web.

A modification of the channel die is the U-bend die (Fig. 6b). Springback is a common problem with this type of die; one means of overcoming it is to perform a secondary operation on flat dies, as shown in Fig. 6(c).

**Air Bending.** In air bending, the die is deep enough that setting does not take place at the bottom of the stroke. The die can have a V shape (Fig. 7), or the sides can be vertical (Fig. 1). The shape and nose radius of the punch are varied to suit the workpiece. The required angle is

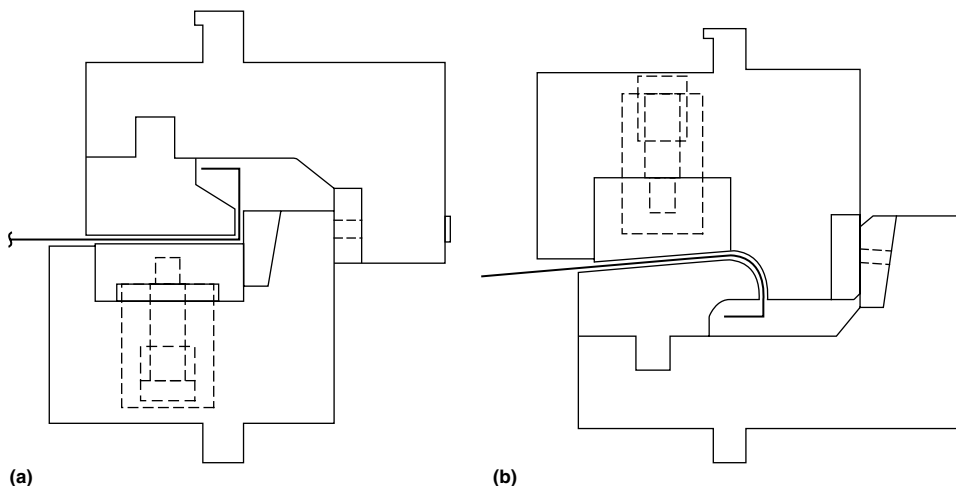

Fig. 5 Wiping dies. (a) Die set for flanging with spring-loaded pressure pad to hold material flat during forming. (b) Die for wiping radius

Fig. 6 Three types of special punches and dies for press-brake forming. (a) Forming a channel in one stroke. (b) Forming a U-bend in one stroke. (c) Flattening to remove springback after U-bending

produced on the workpiece by adjusting the depth to which the punch enters the die opening. This permits the operator to overbend the metal sufficiently to produce the required angle after springback.

When metal is bent beyond its yield strength, the radius formed bears a definite relationship to the opening in the die. A small die opening produces a small radius; the use of a large die opening increases the radius but also increases the amount of springback. Springback must be compensated for by overbending. Changing the size of the die opening also changes the amount of force needed to make the bend. As the die opening is increased, less force is required; as the die opening decreases, the bending leverage is less, and more force is therefore required.

For the air bending of metal up to 13 mm ( $\frac{1}{2}$  in.) thick, the die opening is usually equal to eight times the work metal thickness. This keeps the bend radius approximately equal to the metal thickness. For metal thicker than 13 mm ( $\frac{1}{2}$  in.) and for some high-tensile-strength metals, the die opening should be at least ten times the work metal thickness to increase the bend radius and therefore reduce the possibility of fracture at the bend.

The principal advantage of the air-bend method is the variety of forming that can be done with a minimum number of punches and dies. Air bending also requires less force for a given bend, thus preventing excessive strain on the press brake.

The primary disadvantage of air bending is the possible inconsistency in the bends. Because of variations in dimensions and temper of the work metal as it is received from the mill, springback can vary throughout a production run. However, the operator can adjust the ram to compensate for these irregularities. When air bending in a hydraulic press brake, the operator can use a preset pressure, check each part with a gage, and restrike if necessary. With a mechanical press brake, the shut height can be easily adjusted for a restrike and then reset for the next part.

**Fig. 7** Setup for air bending with an acute-angle punch and die in a press brake

**Box-forming dies** are similar to standard V-dies, except that the punch is sometimes specially made to clear the sides of the box being formed. For square boxes, the punch length can be the inside length, and the sides of the box can be formed in any sequence. However, for the forming of rectangular boxes, different tools or techniques are required. One approach is the use of a punch that is split vertically (Fig. 8) so that the punch can clear the sides on the long dimension while forming the sides of the short dimension. In most cases, however, a punch long enough for forming the long sides can be used without splitting; this is accomplished by forming the short sides first.

When bottoming dies are used in box forming (to overform and coin the metal to reduce springback), the metal can be work hardened excessively if the force used to form the short sides is the same as that used for the long sides. In some shops, when the short sides are less than two-thirds as long as the long sides, force is reduced for forming the short sides.

**Arbor-type punches** can be used when the sides of a boxlike workpiece must be folded over (detail A, Fig. 9). The head of the punch extends beyond the punch body so that the formed-over sides can fit over the punch extensions while the remaining folds are made (Fig. 9). The extensions on the punch are approximately triangular in cross section so that the punch can be withdrawn after opposite sides of the workpiece are closed.

**Lock-Seam Dies.** Lock seams are made in a press brake when quantities are too small to warrant more elaborate equipment. The usual procedure is to form one component with a special punch and die, as shown in Fig. 10(a). The second component of the assembly is formed in a simple V-die. The two components are then locked together in a single stroke of the press brake using another special die (Fig. 10b).

**Fig. 8** Setup for forming a rectangular box using a punch split vertically to clear the long sides during forming of the short sides

**Curling Dies.** Curling in a press brake is usually done in two steps using special dies such as those shown in Fig. 11(a).

**Tube- and pipe-forming dies** resemble curling dies. To ensure that the workpiece rolls up properly, the edges of the metal must initially be bent. Small tubes can be formed by using a two-operation die (Fig. 12a), while larger tubes require the use of a bumping die such as that shown in Fig. 12(b). Where accuracy is required, tubes formed in a bumping die should be sized over a sizing mandrel. If seams are required, they can be formed on the tube edges prior to the rolling operation.

**Rocker-Type Dies.** Dies that operate with spring-actuated rocker punches can produce bends that would be impossible with the punch operating in a vertical direction only. A typical rocker-type die for U-bending is illustrated in Fig. 11(b).

**One-Stroke Hemming Dies.** With specially designed spring-actuated dies, it is possible to hem a length of metal sheet in a single stroke. A typical die used for this operation and the movement of die components required for completing the hem are illustrated in Fig. 13. When provided with an adjustable stop, the die

**Fig. 9** Folding-over sides of a boxlike workpiece using an arbor-type punch for forming beneath reverse flanges. Dimensions given in inches

**Fig. 10** Special punches and dies for producing lock seams in a press brake

shown in Fig. 13 can produce hems of different widths (over a narrow range).

**Beading dies** form beads (stopped ribs) to add rigidity to flat sheets. The dies form either open beads that extend from edge to edge of the sheet or closed beads that fade out in the sheet. The hemispherical depressions that constitute the open bead are formed by the die shown in Fig. 14. Closed beads, on the other hand, necessitate the use of spring-pressure pads at the ends, which fade out to minimize wrinkling of the metal.

Corrugating dies can be used to produce numerous corrugations, as shown in Fig. 15.

**Cam-driven dies**, also known as wedge-driven dies, can be used to increase production rates as well as workpiece quality. When using an acute-angle die at normal press speeds, the sheet travels in a large arc, causing a bend at the outside die edge. This problem can be solved by decreasing the speed of the operation, but a better solution is to use a cam-driven die to ensure that the sheet will lay flat while maintaining the press speed at the desired rate.

## Dies for Shearing, Lancing, Blanking, Piercing, and Notching

Shearing can be done in a press brake, but holdowns and knife supports must be used to obtain reasonable accuracy. For optimal results, a shearing machine should be used (see the article "Shearing of Sheet, Strip, and Plate" in this Volume). There are, however, applications in which shearing in a press brake is convenient because it can be combined with another operation.

**Lancing** is often done in a press brake. An example is the production of louvers, which are used in cabinet or locker doors. The punch, die, and die pad used for the simultaneous lancing and forming of sheet metal into louvers are shown in Fig. 16.

**Blanking.** When long, narrow dies are required for a given application, metal can be blanked in a press brake if adequate support can be provided by the dies or the press brake. The removal of long, narrow workpieces is sometimes a problem. Spring-type or rubber strippers can be added if excessive adherence to the punches is encountered.

**Piercing and Notching.** Press brakes are extensively used for piercing (punching) and notching. A press brake is more practical than a punch press for the piercing or notching of long, narrow workpieces, such as flats, channels, or other cross-sectional shapes. Press brakes are especially well adapted to piercing holes close to the edge of long panels or to notching the edges. Quick-change punching units help to extend the versatility of a press brake for piercing and notching. These punching units can be quickly changed to accommodate different workpieces by using setup templates.

## Rotary Bending

Wiping dies, V-dies, and U-dies have traditionally been used in press-brake forming. Rotary bending is gaining wide acceptance in industry because it significantly reduces the time required to bend materials. Rotary bending is accomplished by using a tool that simultaneously holds and bends the material.

Key components of a rotary bender are the saddle (punch), the adjustable rocker, and the die anvil. The cylindrical rocker features an 88° V-notch cut out along its full length. To minimize marking, the edges of the rocker jaws are flattened and radiused. Figure 17 illustrates the three stages of a rotary-bending operation. Initially (Fig. 17a), the material is clamped, and the rocker rotation begins. Figure 17(b) shows how humping is controlled and confined to the space between the rocker edges. The final step (Fig. 17c) shows how the rocker clamps the workpiece in place and

overbends it sufficiently to compensate for springback.

Rotary benders have been primarily used in conjunction with progressive dies to form Z-bends and short-leg bends in a single operation. Also, dart stiffeners can be rolled into the workpiece simultaneously as it is being bent.

## Selection of Tool Material

Selection of tool material for punches and dies used in press brakes depends on the composition of the work metal, the shape of the workpiece (severity of forming), and the quantity to be produced. The tool material used for press-brake bending and forming ranges from hardwood to carbide, although the use of carbide has usually been confined to inserts at high-wear areas. Hardwood and carbide represent the rare extremes; hardwood is suitable only for making a few simple bends in the most formable work metal, and carbide would be considered only for making severe bends in a less-formable work metal (such as high-strength low-alloy steel) in high production.

**Simple Bending.** Most dies and punches used for simple V-bending operations are made from low-carbon steel (such as 1020) or gray iron. Both of these materials are inexpensive and give acceptable tool life in mild service.

If production runs are long or if the work metal is less formable, some upgrading of the tool material may be desired to retain accuracy over a longer period. Gray iron can be upgraded without adding greatly to tool cost by making both punch and die from a hardenable grade (such as ASTM class 40) and then flame hardening the nose of the punch and the upper edges (high-wear areas) of the V-die to 450 to 550 HB. Low-carbon steel tools can be upgraded by changing to a hardenable grade of steel (such as 1045). High-wear portions of the tools can be flame hardened (usually to 50 to 55 HRC) in the same manner as the gray iron tools.

**Severe Bending.** As the severity of bending and forming increases, such as in producing channels in a single stroke (Fig. 6a), tool materials should be upgraded when more than low-production quantities are needed. For operations that require severe bending, tool material

Fig. 11 Special punches and dies for curling and U-bending in a press brake

Fig. 12 Tube- and pipe-forming dies. (a) Two-operation die for the forming of small tubes. (b) Bumping die used to form large tubes

requirements for press-brake operations parallel those for punch-press operations (see the article "Selection of Materials for Press-Forming Dies" in this Volume).

**Blanking and piercing** are done in a press brake with tools of the same materials as those used in punch presses (see the article "Selection of Materials for Shearing, Blanking, and Piercing Tools" in this Volume).

**Rubber Pads.** The use of rubber pads in press-brake dies (Fig. 18) enables the forming of shapes that are difficult or impossible to form

without the pads. The pads also minimize damage to work metal surfaces and decrease die cost. Additional information is available in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

Urethane rubber is the type most widely used. Pads inserted into the bottom of the die can be used for forming V and channel sections in various metals ranging from soft aluminum to low-carbon steel up to 12 gage (2.657 mm, or 0.1046 in.) in thickness. When using the urethane-pad technique, the urethane is, in effect,

the die. It is almost impossible to compress urethane; its shape changes but not its volume. With minimum penetration of the punch, the pad begins to deflect, exerting continuous forming pressure around the punch. At the bottom of the stroke, the urethane has assumed the shape of the punch. When the pressure is released, the pad returns to its original shape.

**Fig. 13** One-stroke hemming die and movement of die components during hemming. (a) Workpiece, B, is placed over slide A using a component of the die as a stop, and the entire upper die section begins to move down. (b) Slide C contacts the workpiece and makes the first bend for the hem. (c) With slide D holding the workpiece rigidly in place, die component E forces slide A to the left, forming the bent section of the workpiece into an acute angle. (d) As the die continues to move down, die component E permits slide A to retract, providing clearance for F to contact and flatten the workpiece as it forces slide C to the left, thus completing the hem. On the upstroke of the press brake, die components return to original positions.

**Fig. 17** Sequence of operations illustrating rotary bending in a press brake. (a) Material is clamped, and rocker rotation begins. (b) Humping is controlled and limited to space between edges of rocker. (c) Workpiece is clamped in position by rocker and overbent to allow for springback.

Urethane pads are generally used for short-run production. However, in one plant, 14,000 boiler-casing channels were formed from 16 gage (1.52 mm, or 0.0598 in.) low-carbon steel in 4.9 m (16 ft) lengths on the same urethane pad before replacement.

Urethane robber is made in several different grades ranging in tensile strength from 18 to 76 MPa (2600 to 11,000 psi) and in hardness from durometer 80A to 79D. (Additional information is available in the article "Miscellaneous Hardness Tests" in *Mechanical Testing and Evaluation*, Volume 8 of *ASM Handbook*, 2000). Selection of grade depends on work metal hardness and thickness and on severity of forming. Experimentation is often needed to determine the optimal grade of urethane for the application.

**Work Metal Finish.** When preservation of work metal finish is a primary objective, the dies or punches or both are sometimes chromium plated. Other means of preserving the work metal finish include the use of oil-impregnated paper between the tools and the work metal, or spraying the tools with a plastic of the type used to coat metal sheets for deep drawing.

## Procedures for Specific Shapes

Procedures and tooling for press-brake operations vary widely and are mainly influenced by workpiece shape. The following examples describe the procedures used for producing several different shapes, including simple boxlike parts, panels, flanged parts, architectural columns, fully closed parts, and semicircular parts.

**Example 2: Four-Stroke Forming of Closed-Bottom Boxes from Notched Blanks.** Closed-bottom boxes were produced from 1010 steel blanks sheared to 508 by 610 mm (20 by 24 in.)

in a press brake. The four corners were notched to a depth of 102 mm (4 in.) in a standard notching die in the same press brake as that used to make the blanks. The box was then formed in four strokes of the press brake, using a standard 90° V-die but with a deeper-than-normal punch (Fig. 19). By bending the 305 mm (12 in.) sides first, all four bends could be made with a die 406 mm (16 in.) long. Hourly production rates for the three operations were:

Operation	Pieces
Shear blanks	55
Notch corners (four strokes)	57
Bend from sides (four strokes)	44

**Example 3: Six-Operation Forming of an Architectural Column.** An architectural column 3 m (10 ft) long was produced in six operations in a press brake. Figure 20 shows the sequence of shapes produced. Channel dies were used for operations 1 and 2. Operation 3 required a special punch and die for producing the large-radius bends. A simple channel die was used for operation 4, and a V-die for operation 5. Operation 6 was performed with a gooseneck punch that was necked-in sufficiently to clear the edge flanges as the part closed in.

The major problem in forming this shape was to obtain sharp 90° bends at all corners and to keep the flanges in the same plane. Because the part was 3 m (10 ft) long, considerable shimming of the tools was required to produce satisfactory parts.

**Correct shimming** is a major factor in maintaining accuracy when producing shapes in a press brake such as that shown in Fig. 20. Shims are required to adjust for the discrepancies between bed plate and bolster. Also, deflections produced by the punch bottoming on all hits will

be greater in the center of the die than at the edges, and shimming is required to equalize the pressure along the entire length of the bend. Optimal shimming is accomplished mainly by trial and error, because of the variations among machines, tools, and workpieces.

**Example 4: Producing a Completely Closed Triangular Shape.** Figure 21 shows the four separate setups that were used to produce an 865 mm (34 in.) long completely closed triangular part in a press brake. The 540 by 865 mm (21<sup>9</sup>/<sub>32</sub> by 34 in.) blanks were prepared by shearing on separate equipment. As shown in Fig. 21, the first press-brake operation produced a 90° bend, and the second operation produced a 68° bend; simple straight-sided punches were used for both bends. In the third operation, a special punch 30 mm (1<sup>1</sup>/<sub>8</sub> in.) thick and having an offset nose was used to produce a 32° bend. By bending only to 32°, sufficient space was allowed for withdrawal of the punch. The punch had an offset nose because of the off-center seam location (a design requirement); if the seam had been centered, the punch would have been symmetrical. In the fourth operation, the part was closed. The part just before the fourth operation

**Fig. 18** Setups for rubber pad forming of various shapes in a press brake. (a) Simple 90° V-bend. Air space below die pad permits deep penetration. (b) Simple U-bend or channel. Spacers enable channels of varying widths to be formed in the same die-pad retainer. Deflector bars help to provide uniform distribution of forming pressure. (c) Modified channel, with partial air bending. (d) Acute-angle channel. High side pressures are obtained by using a conforming rubber die pad and deflector bars.

**Fig. 20** Shapes progressively produced in six-operation forming of an architectural column in a press brake using 1.21 mm (0.0478 in.) thick steel sheet

is shown at the upper right-hand corner in Fig. 21. Time to complete the four operations was just under 1 min. Total time per part was just over 1 min, with a production rate of 58 parts per hour.

**Semicircular Shapes and U-Bends.** Flat stock can be formed into semicircular shapes and U-bends in a press brake. If the press capacity is adequate for the work metal thickness and the dimensions required, forming can be done in one operation, as in 90° V-bending. As shown in Fig. 6(b), the radius of the punch nose forms the inside radius of the workpiece.

Air bending is used to form semicircular shapes and U-bends when the work metal thickness and the dimensions exceed press capacity. A typical setup is shown in Fig. 22. Starting from the end of the workpiece at the right, and a distance of half the span of the die opening, pairs of equally spaced center-punch marks are made near each side of the workpiece, progressing to the left in two straight lines at 90° to the bend axis. These two rows of punch marks guide the operator in maintaining the alignment of the bend.

To form the part, the blank is placed across the die opening with the center-punch marks facing up, so that the punch will contact the blank at the first pair of punch marks. A bend is made at each pair of punch marks progressively toward the center of the blank (Fig. 22). When the center is reached, a quarter circle will have been formed. The blank is rotated 180°, and the procedure is repeated until a semicircle is formed. The radius of the semicircle will depend on the amount of bending done with each blow of the press and on the distance between the punch marks.

Bending should always proceed from the end of the blank toward the center in order to avoid interference between the ram and the formed workpiece. After forming, the straight section at each end of the workpiece is sheared off. The following example describes an application of this procedure for producing semicircular parts by air bending.

**Example 5: Forming Semicircular Parts by Air Bending.** Two semicircular parts were formed from 19 mm (3/4 in.) thick low-carbon

steel plate, and the parts were welded together to produce a 255 mm (10 in.) outside diameter hollow cylinder 255 mm (10 in.) long. Blank size for each semicircular part was 255 by 470 mm (10 by 18 1/2 in.). The bend length required for each part was 370 mm (14 1/2 in.), but the blanks were cut to 470 mm (18 1/2 in.) to allow for trimming after forming (Fig. 22).

Before forming, two rows of center-punch marks were made on the blanks (Fig. 22). The first mark was 50 mm (2 in.) from the blank edge, with subsequent marks every 13 mm (1/2 in.) of the 370 mm (14 1/2 in.) bend length.

The parts were formed in an 1800 kN (200 tonf) mechanical press brake using a standard V-die and round-nose punch. Thirty bends were required to form each semicircular part. After several bends, the curve was checked with a template to determine the accuracy of the bend. After forming a quarter of the circle, the workpiece was rotated 180°, and the operation was repeated to complete the half circle. The final bend was made at the center of the workpiece. The 50 mm (2 in.) allowance at each end of the workpiece was then sheared off.

**Corrugated Sheet.** Special procedures allow bends to be fabricated in corrugated metal that are perpendicular to the corrugations, without flattening the corrugations. This can be achieved by using cast-on plastic blankets.

## Effect of Work Metal Variables on Results

Thickness variations, yield strength, and rolling direction are the work metal variables that have the greatest effect on results in press-brake operations. Whenever possible, any metal to be formed should be purchased only to commercial tolerances; special tolerances increase cost. However, when workpiece tolerances are close, it is sometimes necessary to purchase metal with special thickness tolerances, because normal variations can use up a substantial amount of the assigned final tolerance (see the section "Dimensional Accuracy" in this article).

**Yield Strength.** As the yield strength of the work metal increases, so does the difficulty in bending. This difficulty occurs as cracking at the bends, increased power requirements, or an increase in springback.

For example, bending of stainless steel requires approximately 50 to 60% more power than bending a comparable thickness of low-carbon steel. Because of its resistance to bending, stainless steel often causes difficulty in obtaining acceptable results (see the article "Forming of Stainless Steel" in this Volume).

**Springback.** In a wiping type of bending operation, in which the metal is bent to position but the corner is not coined to set the bend, the metal attempts to return to its original position. This movement, known as springback, is evident to some extent in all metals, and it increases with the yield strength of the metal. The amount of springback is usually negligible for a soft metal such as 1100 aluminum alloy. However, for aluminum alloys such as 2024, the amount of springback can be significant. In general, low-carbon steels exhibit more springback than aluminum or copper alloys do, and still more springback can be expected for stainless steel.

A common technique for overcoming springback is to overbend by approximately the number of degrees of springback. Several trials in tool development may be needed to obtain the proper angle, because of variations in mechanical properties, work-hardening rate, metal thickness, and die clearances. Springback from one bend can sometimes be used to offset that from another. Tables and graphs for springback have been developed for specific metals. Detailed information on the subject of springback is also addressed in the article "Springback" in this Volume.

Another technique for overcoming springback is the use of specially designed bottoming dies that strike the workpiece severely at the radius of the bend. This action stresses the metal in the bend area beyond the yield point through almost the entire thickness and thus eliminates springback. Bottoming must be carefully controlled, particularly if it is done in a mechanical press brake, because the force developed by this machine can be very high.

**Fig. 21** Sequence of operations for forming a closed triangle in a press brake. Dimensions given in inches

**Fig. 22** Air bending to form a semicircular part by progressive strokes of the punch

Restriking in the original dies or special fixtures will reduce springback to a low level. It requires an additional operation but may entail little or no additional equipment. In the following example, a second stroke was used.

**Example 6: Correcting Springback in the Forming of a Complex Shape.** The shape shown at the lower right-hand corner in Fig. 23 was produced from 0.91 mm (0.036 in.) thick 1010 steel in lengths ranging from 0.9 to 2.4 m (3 to 8 ft). The five operations used in producing the part are shown in Fig. 23(a) to (e). The box section was formed by a wiping action (Fig. 23d) with no force on the outermost portion of the box. Consequently, springback occurred and required another step to correct by overforming (Fig. 23e). The shut height of the die was adjusted to provide the correction.

**Rolling Direction.** In the press-brake forming of steel, the effect of rolling direction is often a greater problem than in other methods, because long members are usually bent in a press brake and bends are made with axes parallel to the rolling direction, which is the least favorable orientation. However, it is sometimes possible to take advantage of directionality. The most severe bends can be made perpendicular to the direction of rolling, or if several bends are required along axes that are not parallel with each other, the layout can be planned so that all bends run diagonally to the direction of rolling. The difference in behavior of the same steel bent in both directions in a press brake is demonstrated in the following example.

**Example 7: Effect of Rolling Direction on Bending.** An axle bearing support was produced in four bends (Fig. 24) in a press brake using standard 90° V-dies. Cracks could not be

tolerated. No cracks appeared on the flanges formed on the short dimensions, which were bent 90° to the direction of rolling to a 6 mm (1/4 in.) radius. However, in bending the flanges on the long dimensions, parallel with the direction of rolling, open breaks appeared along the length of the bend. To prevent this cracking, it was necessary to increase the bend radius on the long dimensions to 13 mm (1/2 in.) and to prepare the blanks so that the long flanges were formed at a slight angle to the direction of rolling.

**Relation Between Bend Angle and Rolling Direction.** As the thickness and yield strength of the work metal increase, the relationship between bend angle and grain direction becomes more important. For example, when stock thickness reaches approximately 25 mm (1 in.) and the yield strength is relatively high, as in high-strength low-alloy steels, the bend radius should be at least twice (and preferably three times) the stock thickness, even for bends of no more than 45°, when the bend axis is parallel with the direction of rolling.

In the press-brake forming of long, narrow workpieces, bending at an angle to the direction of rolling is seldom practical. For such work, the use of steel sheet that has been cross rolled or subjected to a pinch pass is a simple but relatively expensive means of minimizing the adverse effects from grain direction.

## Dimensional Accuracy

The generally accepted tolerance for dimensions resulting from bending is  $\pm 0.4$  mm ( $\pm 0.016$  in.) for metals up to and including 3.2 mm (0.125 in.) thick. For thicker metals, the tolerance is increased proportionately. As in

many other mechanical operations, obtainable tolerances are influenced by design, stock tolerances, blank preparation, and condition of the machine and tooling. In some cases, close control of variables can provide closer dimensions at no additional cost; in others, cost will be increased.

**Design.** Bends or holes too close to the workpiece edges make it difficult to maintain an accurate bend line. Notches and cutouts on the bend line make it difficult to hold accurate bend location. Offset bends will shift unless the distance between bends in the offset is at least six times the thickness of the work metal.

**Stock tolerances** affect the dimensional accuracy of the finished part because they use up a portion of the assigned final tolerance. Commercial tolerances, particularly on thickness to which the specified metal is furnished, should be ascertained. For aluminum, there are minor differences in thickness limits between clad and unclad alloys. For steels, there are significant differences both in thickness tolerances and in cost among hot-rolled sheet, hot-rolled strip, cold-rolled sheet, and cold-rolled strip.

Cold-rolled steel sheet is produced to closer tolerances than hot-rolled sheet, but its cost is higher. Tolerances on steel strip, either hot rolled or cold rolled, are closer than those for corresponding sheet. Established tolerances are closer as the product becomes narrower or thinner.

Thickness tolerances for steel plate are considerably wider than those for hot-rolled steel sheet and strip. When ordered to thickness, the allowable minimum is 0.25 mm (0.010 in.) less than that specified, regardless of thickness, and the allowable maximum for an individual plate is  $1\frac{1}{3}$  times the values that are published by the mills and expressed as a percentage of the nominal weight. Therefore, when tolerance requirements are stringent, it should be determined whether the metal can be obtained as strip or sheet rather than as plate.

**Blank preparation** can have an important effect on the tolerances and the cost of the finished part. If a blank is prepared by merely cutting to length from purchased stock, it will be low in cost, but the width tolerance will be that of the mill product. This may be greater than the tolerance obtainable by shearing. If it is necessary to shear all sides of a blank, the cost will increase, but good shearing can result in greater accuracy.

**Fig. 23** Setups and sequence of operations for forming a complex shape in a press brake showing use of a restriking operation to eliminate springback. (a) Forming hem in two strokes. (b) Forming of first 90° angle for box section. (c) Forming channel. (d) Closing of box section over a mandrel. Part was moved by sliding it off mandrel. (e) Restriking of box section to eliminate springback. Dimensions given in inches

**Fig. 24** Axle bearing support for which blank was prepared so that long flanges were formed at a slight angle to direction of rolling to prevent cracking. Dimensions given in inches

The stock from which blanks are cut must be flat enough for the blanks to be properly inserted into tooling and to remain in position during forming. Stretcher-leveled and resquared sheet costs a little more, but it is usually necessary when tolerances are close.

**Blank Size.** To determine the size of the blank needed to produce a specified bent part, the blank dimension (usually, the blank width) at 90° to the bend axis can be developed on the basis of the dimension along the neutral axis.

For 90° bends, as shown in Table 2, the developed blank width can be obtained by deducting bend allowances from the theoretical distance along the outside mold line. These allowances take into account the type and thickness of the work metal and the bend radius—each of which can affect the location of the neutral axis and therefore the developed width. The application of these allowances, which are based on shop practice with low-carbon steel and aluminum alloy 5052, is shown in the illustration in Table 2, for parts having one, two, three, or four bends.

For setting the stock stops from the centerline of the punch and die, the distance from the edge of the workpiece to the bend line at the neutral axis (Table 2) must be determined. To establish this value for 90° bends, subtract one-half the bend allowance from the outside flange width.

For bend angles other than 90° or radii other than those listed in Table 2, the width of a strip needed to produce a given shape can be calculated by dividing the shape into its component straight and curved segments and totaling the developed width along the neutral axis. Equation 3 can be used to determine the developed width,  $w$ , of a curved segment:

$$w = 0.01745 \alpha (r + kt) \quad (\text{Eq 3})$$

where 0.01745 is a factor to convert degrees to radians;  $\alpha$  is the included angle to which the metal is bent (in degrees);  $r$  is the inside radius of the bend (in inches); and  $k$  is the distance of neutral plane or axis from the inside surface at the bend expressed as the fraction of the metal thickness,  $t$ , at the bend. Empirically determined values of  $k$  are:  $1/3$ , for bends of radius less than  $2t$ ; and  $1/2$ , for bends of greater radius. Sample calculations showing the use of Eq 3 are presented in the article "Contour Roll Forming" in this Volume.

**Permissible bend radii** depend mainly on the properties of the work metal and on tool design. For most metals, the ratio of minimum bend radius to thickness is approximately constant, because ductility is the primary limitation on minimum bend radius. Another complicating factor is the effect of work hardening during bending, which will vary with metal and heat treatment.

**Condition of Machines and Tools.** Machines and tools must be kept in the best possible condition for maintaining close dimensions in the finished product. General-purpose tooling is seldom built for precision work and is frequently given hard use, which contributes further to inaccuracy through wear. Uneven wear aggravates the condition. If the press brake has been allowed to become loose and out-of-square and if ram guides and pitman bearings are worn, accurate work cannot be produced. Good maintenance is as essential in successful press-brake operation as in any other mechanical process.

## Press-Brake Forming versus Alternative Processes

For many applications, press-brake forming is the only practical method of producing a given shape. In one case, for example, press-brake forming was used for a massive workpiece 3 to 3.7 m (10 to 12 ft) long that required several bends spaced at least 152 mm (6 in.) apart.

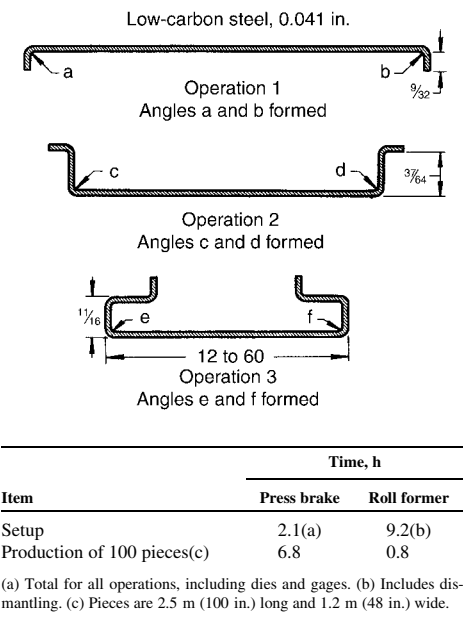

Under certain conditions, either a punch press or a contour roll former will compete with a press brake in performance and economy. When a workpiece can be produced by two or all of these methods, the choice will depend mainly on the

**Table 2 Bend allowances for 90° bends in low-carbon steel and aluminum alloy 5052**

Metal thickness ( $t$ )		Bend allowance, mm (in.), for bends with inside radius ( $r$ ) of:

**Fig. 25** Workpiece formed in six bends in either a press brake or a ten-station contour roll former. Dimensions given in inches

quantity to be produced and the availability of the equipment.

**Press Brake versus Punch Press.** When a given workpiece can be made to an equal degree of acceptability in either a press brake or a punch press, the punch press is usually more economical, and it is more efficient than the press brake in terms of power requirements for a given force on the ram and number of strokes per unit of time. In addition, air ejection is more readily adapted to a punch press than to a press brake; this is a factor when air is required for ejecting either the workpiece or scrap.

The advantages of a punch press over a press brake are generally greater when production quantities are large and workpieces are relatively small. As workpiece size increases, the advantages of a punch press diminish.

Tooling for a press brake is usually simpler and less costly than counterpart tooling for a

punch press—an important consideration for small production quantities. One disadvantage of punch presses is that they are more sensitive to thickness variations of the work metal because they operate at a faster rate.

**Press-Brake versus Contour Roll Forming.** For many parts usually formed in a press brake, contour roll forming is an acceptable alternative method of production, and the choice between the two processes depends mainly on the quantity to be formed. Press-brake forming is adaptable for quantities ranging from a single piece to a medium-sized production run, while contour roll forming is usually restricted to large-quantity production because of higher tooling costs. An advantage of contour roll forming is that coil stock can be used, while cut-to-length stock must be used in a press brake (see the article “Contour Roll Forming” in this Volume). The following example compares the efficiency of press-brake forming and contour roll forming.

**Example 8: Press-Brake Forming versus Contour Roll Forming.** Parts were produced to the shape shown in Fig. 25 in lengths up to 3.7 m (12 ft) and widths varying from 0.30 to 1.5 m (12 to 60 in.). The six bends were originally made in a press brake in three operations. When quantity requirements increased, production was changed to contour roll forming in a ten-station machine, from sheared-to-size sheets. Contour roll forming not only decreased the production time (table, Fig. 25) but also resulted in improved surface finish, because less handling of the work metal was required.

**Safety**

Press-brake operations involve the hazards of other press operations. Proper feeding devices are vital in order to ensure the safety of the press operator. Because more than one operator is often needed, added precautions are necessary to prevent the operation of a press brake without the direct consent of each man.

The article “Presses and Auxiliary Equipment for Forming of Sheet Metal” in this Volume

contains information and literature references on safe operation. Some of the precautions noted are discussed as follows.

Barrier guards should be used wherever possible. Hand feeding devices such as vacuum lifters, special pliers, or magnetic pickups should always be used to keep operators’ hands clear of dies.

When a large workpiece extends in front of the die, the operator often must use his hands to support the workpiece during forming. If a barrier guard cannot be used, because of the arc of travel of the front leg during forming or because the workpiece is of such shape that a guard would prevent loading or unloading of the workpiece, the sheet should be inserted against back gages. These gages, or stops, are adjusted so that the workpiece cannot slide over them.

The workpiece is supported by hand only if there is no other way to support it, and even then only if the operator’s hands are not within reach of the die or any pinch point. A die apron or table should be provided to aid in loading large sheets into the die and to act as a support for sheets that do not require hand support. The formed sheet should be removed from the front of the press; parts that cannot be unloaded from the front of the press are moved to the end for removal. End supports may be required to prevent the workpieces from falling.

For versatility, a press brake is provided with a foot pedal to operate the machine. The foot pedal must have a cover guard so the press cannot be tripped accidentally. A foot-operated press brake should incorporate a single-stroke mechanism and be used as a single-operator machine.

When a press brake is used as a power press for stamping, shearing, and notching operations, the foot pedal should not be used. Instead, the press brake should be equipped with electropneumatic clutch and brake controls and should be provided with a single-stroke device. The foot pedal is replaced with two-hand palm switches, which are spaced so that the operator must use both hands to hold the switches until the die is closed. If a press brake is used exclusively for press work, the foot pedal should be permanently removed.

# Deep Drawing

Revised by Mahmoud Y. Demeri, FormSys, Inc.

DEEP DRAWING of sheet metal is used to form parts by a process in which a flat blank is constrained by a blankholder while the central portion of the sheet is pushed into a die opening with a punch to draw the metal into the desired shape without causing wrinkles or splits in the drawn part. This generally requires the use of presses having a double action for hold-down force and punch force. The mechanics of deep drawing of a conical cup are illustrated in Fig. 1, which shows the complexity of the process. Deep drawing involves many types of forces and deformation modes, such as tension in the wall and the bottom, compression and friction in the flange, bending at the die radius, and straightening in the die wall. The process is capable of forming beverage cans, sinks, cooking pots, ammunition shell containers, pressure vessels, and auto body panels and parts. The term *deep drawing* implies that some drawing-in of the flange metal occurs and that the formed parts are deeper than could be obtained by simply

**Fig. 1** Mechanics of the deep drawing of a cylindrical cup

stretching the metal over a die. Clearance between the male punch and the female die is closely controlled to minimize the free span so that there is no wrinkling of the sidewall. This clearance is sufficient to prevent ironing of the metal being drawn into the sidewall of the drawn part. If ironing of the walls is to be part of the process, it is done in operations subsequent to deep drawing.

Suitable radii in the punch bottom to side edge, as well as the approach to the die opening, are necessary to allow the sheet metal to be formed without tearing. In most deep-drawing operations, the part has a solid bottom to form a container and a retained flange that is trimmed later in the processing. In some cases, the cup shape is fully drawn into the female die cavity, and a straight-wall cup shape is ejected through the die opening. To control the flange area and to prevent wrinkling, a hold-down force is applied to the blank to keep it in contact with the upper surface of the die. Presses used for deep-drawing operations can be either hydraulic or mechanical, but hydraulic presses are preferred because of better control of the rate of punch travel.

Any metal that can be processed into sheet form by a cold-rolling process should be sufficiently ductile to be capable of deep drawing. Both hot- and cold-rolled sheet products are used in deep-drawing processes. The cold-work effects introduced during processing of the sheet products for deep-drawing applications must be removed (by annealing, for example), and the as-delivered coils should be free of any aging. This would imply that aluminum-killed drawing-quality steel, for example, would be preferred over rimmed steel. After the deep-drawing operation, ductility can be returned to that of the original sheet by in-process annealing, if necessary. In many cases, however, metal that has been deep drawn in a first operation can be further reduced in cup diameter by additional drawing operations, without the need for intermediate annealing.

The properties considered to be important in sheet products designed for deep drawing include:

- Composition, with a minimum amount of inclusions and residual elements contributing to better drawability

- Mechanical properties, of which the elongation as measured in a tension test, the plastic-strain ratio  $r$  (see the section "Drawability" in this article), and the strain-hardening exponent  $n$  are of primary importance. The strength of the final part as measured by yield strength must also be considered, but this is more a function of the application than forming by deep drawing.
- Physical properties, including dimensions, die geometry, modulus of elasticity, and any special requirements for maintaining shape after forming

Once a metal has been deep drawn into a suitable form, it can be further processed to develop additional shape. The first shape is usually a round cylinder, or a modification of this—a square box with rounded corners, for example. This latter shape is related to the cylinder in that the four corners are essentially quarter segments with straight walls between each segment.

For small cylinders, a relationship between the diameter of a circular blank and the bottom diameter of the cup shape to be formed is sometimes used to measure deep drawability. The most commonly referred to cup test for deep drawing is the Swift cup test, which uses a 2 in. (50 mm) diameter flat-bottomed punch to form test blanks. For ductile low-carbon steel, aluminum, and brass sheets, a 100 mm (4 in.) circular blank can be formed in a single draw. Increased plastic strain ratio  $r$  and ductility allow larger blanks to be drawn successfully; the limit is reached when the bottom punches out, rather than forming a cup shape. The blank diameter divided by the punch diameter gives the limiting draw ratio (LDR), which for the previous examples would be 2. More information on the Swift cup test is available in the article "Formability Testing of Sheet Metals" in this Volume.

Of the commonly formed metals, brass and austenitic stainless steels show high limiting draw ratios (up to 2.25). A few samples have reached a value of 2.5 to produce a cup with a sidewall height of nearly 65 mm (2.5 in.). This is possible, although the total length of the cup cross section would be 180 mm (7 in.), which is more than the blank diameter because of the deep-drawing forces. The interstitial-free steels,

which have average  $r$  values of 2.5 or higher, can be deep drawn to limiting draw ratios near 2.5. With these extremely deep draws, sidewall delayed splitting must be prevented by such means as stress-relief annealing immediately following the drawing operation.

The thickness of the work metal does not change appreciably in deep drawing; therefore, the surface area of the final part is approximately the same as that of the initial blank. As the metal in the flange area is drawn into the die opening over the approach radius, it is subjected to radial tension and, concurrently, to circumferential compression. This explains why a 125 mm (5 in.) diameter blank with a surface area of 126 cm<sup>2</sup> (19.6 in.<sup>2</sup>) can form a cup shape 65 mm (2.5 in.) deep that has a total surface area of approximately 121 cm<sup>2</sup> (18.8 in.<sup>2</sup>).

With proper balance among the punch force, the hold-down force, and the strength of the sheet metal being formed, a cup shape can be developed. At the start of this process, the metal in the free area between the punch bottom and the flange hold-down is stretched and wrapped over the nose of the punch and the approach radius of the die. During this stretching, strain hardening strengthens the metal. If it is not capable of such strengthening or if its strength at any location is exceeded at any time during the forming, the bottom of the cup shape will break out. Contributing to this strengthening is a high  $r$  value, which is a measure of resistance to through-thickness changes in the sheet metal. If the metal has a high resistance to thinning and thickening, the bottom radius and the upper sidewall areas remain close to their original thickness, and the radial and circumferential strains obtainable in the drawn-in flange are increased to accommodate the deep-drawing process.

After the bottom has been formed, the clearance between the punch and die is such that the metal in the cup side is free to move without excessive rubbing on the die walls. It has been found that slight roughening of the punch radius and minimizing the lubrication of this area contribute to deeper drawability; however, the die opening should be smooth and well lubricated with a suitable drawing compound.

## Fundamentals of Drawing

A flat blank is formed into a cup by forcing a punch against the center portion of a blank that rests on the die ring. The progressive stages of metal flow in drawing a cup from a flat blank are shown schematically in Fig. 2. During the first stage, the punch contacts the blank (Fig. 2a), and metal section 1 is bent and wrapped around the punch nose (Fig. 2b). Simultaneously and in sequence, the outer sections of the blank (2 and 3, Fig. 2) move radially toward the center of the blank until the remainder of the blank has bent around the punch nose and a straight-wall cup is formed (Fig. 2c and d). During drawing, the center of the blank (punch area, Fig. 2a) is

essentially unchanged as it forms the bottom of the drawn cup. The areas that become the sidewall of the cup (1, 2, and 3, Fig. 2) change from the shape of annular segments to longer parallel-side cylindrical elements as they are drawn over the die radius. Metal flow can occur until all the metal has been drawn over the die radius, or a flange can be retained.

A blankholder is used in a draw die to prevent the formation of wrinkles as compressive action rearranges the metal from flange to sidewall. Wrinkling starts because of some lack of uniformity in the movement or because of the resistance to movement in the cross section of the metal. This happens because metal under compression has a great resistance to flow into the die cavity. A blankholder force sufficient to resist or compensate for this nonuniform movement prevents wrinkling. Once a wrinkle starts, the blankholder is raised from the surface of the metal so that other wrinkles can form easily. The force needed to hold the blank flat during drawing of cylindrical shells varies from practically zero for relatively thick blanks to approximately one-third of the drawing load for a blank 0.76 mm (0.030 in.) thick. Thinner blanks often require proportionally greater blankholder force.

Conditions for drawing without a blankholder depend on the ratio of the supported length of the blank to its thickness, the amount of reduction from blank diameter to cup diameter, and the ratio of blank diameter to stock thickness. For thick sheets, the maximum reduction of blank diameter to cup diameter in drawing without a blankholder is approximately 25%. This ratio approaches zero for thin foil-like sheet. If a blankholder is employed, the maximum reduction is increased to approximately 50% for metals of maximum drawability and 25 to 30% for metals of marginal drawability in the same equipment. More information on the effect of blank thickness on drawing is in the article "Design for Sheet Forming" in this Volume.

## Drawability

In an idealized forming operation, that is, one in which drawing is the only deformation process that occurs, the blankholder force is just sufficient to permit the sheet material to flow radially into the die cavity without wrinkling. Deformation takes place in the flange and over the lip of the die. No deformation occurs over the nose of the punch. The deep-drawing process can be thought of as analogous to wire drawing in that a large cross section is drawn into a smaller cross section of greater length.

The drawability of a metal depends on two factors:

- The ability of the material in the flange region to flow easily in the plane of the sheet under shear
- The ability of the sidewall material to resist deformation in the thickness direction

The punch prevents sidewall material from changing dimensions in the circumferential direction; therefore, the only way the sidewall material can flow is by elongation and thinning. Thus, the ability of the sidewall material to withstand the load imposed by drawing down the flange is determined by its resistance to thinning, and high flow strength in the thickness direction of the sheet is desirable.

Taking both of these factors into account, it is desirable in drawing operations to maximize material flow in the plane of the sheet and to maximize resistance to material flow in a direction perpendicular to the plane of the sheet. Low flow strength in the plane of the sheet is of little value if the work material also has low flow strength in the thickness direction.

The flow strength of sheet metal in the thickness direction is difficult to measure, but the plastic-strain ratio  $r$  compares strengths in the plane and thickness directions by determining true strains in these directions in a tension test. For a given metal strained in a particular direction,  $r$  is a constant expressed as:

$$r = \epsilon_w / \epsilon_t \quad (\text{Eq 1})$$

where  $\epsilon_w$  is the true strain in the width direction, and  $\epsilon_t$  is the true strain in the thickness direction. Sheet metal is anisotropic; that is, the properties of the sheet are different in different directions. It is, therefore, necessary to use the average of the strain ratios measured parallel to, transverse to, and 45° to the rolling direction of the sheet to obtain an average strain ratio  $\bar{r}$ , which is expressed as:

$$\bar{r} = r_L + 2r_{45} + r_T / 4 \quad (\text{Eq 2})$$

where  $r_L$  is the strain ratio in the longitudinal direction,  $r_{45}$  is the strain ratio measured at 45° to the rolling direction, and  $r_T$  is the strain ratio in the transverse direction.

If flow strength is equal in the plane and thickness directions of the sheet,  $\bar{r} = 1$ . If strength in the thickness direction is greater than average strength in the directions in the plane of the sheet,  $\bar{r} > 1$ . In this latter case, the material resists uniform thinning. Generally, the higher

Fig. 2 Progression of metal flow in drawing a cup from a flat blank

the  $\bar{r}$  value, the deeper the draw that can be achieved (Fig. 3).

Because the average strain ratio  $\bar{r}$  gives the ratio of average flow strength in the plane of the sheet to average flow strength normal to the plane of the sheet, it is a measure of normal anisotropy. Variations of flow strength in the plane of the sheet are termed planar anisotropy. The variation in strain ratio in different directions in the plane of the sheet,  $\bar{r} > 1$ , is a measure of planar anisotropy, and  $\bar{r}$  can be expressed as:

$$\bar{r} = r_L + 2r_{45} = r_T/4 \quad (\text{Eq 3})$$

where  $r_L$  is the variation in strain ratio, and the other terms are as defined in Eq 2.

A completely isotropic material would have  $\bar{r} = 1$  and  $\Delta r = 0$ . These two parameters are convenient measures of plastic anisotropy in sheet materials. More information on formability is available in the article "Formability Testing of Sheet Metals" in this Volume.

**Drawing Ratios.** Drawability can also be expressed in terms of a limiting draw ratio or percentage of reduction based on results of Swift cup testing (see the article "Formability Testing of Sheet Metals" in this Volume). The limiting draw ratio is the ratio of the diameter  $D$  of the largest blank that can be successfully drawn to the diameter of the punch  $d$ :

$$\text{LDR} = \frac{D}{d} \quad (\text{Eq 4})$$

Percentage of reduction would then be defined as:

$$\text{Percentage of reduction} = \frac{100(D-d)}{D} \quad (\text{Eq 5})$$

Additional information on formability testing and other measures of formability is available in the article "Formability Testing of Sheet Metals" in this Volume.

## Defects in Drawing

A number of defects may occur in deep-drawn parts. Figure 4 shows the type of defects that may be found after drawing cylindrical cups. The following is a description of such defects:

- **Earing:** Occurs in deep-drawn parts made from anisotropic materials. Because of planar anisotropy, the sheet metal may be stronger in one direction than in other directions in the plane of the sheet. This causes the formation of ears in the upper edge of a deep-drawn cup even when a circular blank is used. In practice, enough extra metal is left on the drawn cup so that the ears can be trimmed.
- **Wrinkling in the flange:** Wrinkling in deep-drawn parts consists of a series of ridges that form radially in the flange due to compressive forces.
- **Wrinkling in the wall:** Occurs when ridges in the flange are drawn into the vertical wall of the cup

- **Tearing:** Occurs near the base of the drawn cup and results from high stresses in the vertical wall that cause thinning and failure of the metal at that location
- **Surface scratches:** Occur in a drawn part if the punch and die surfaces are not smooth or if lubrication is not enough

## Presses

Sheet metal is drawn in either hydraulic or mechanical presses. Double-action presses are required for most deep drawing because a more uniform blankholding force can be maintained for the entire stroke than is possible with a spring-loaded blankholder. Double-action hydraulic presses with a die cushion are often preferred for deep drawing because of their constant drawing speed, stroke adjustment, and uniformity of clamping pressure. Regardless of the source of power for the slides, double-action straight-side presses with die cushions are best for deep drawing. Straight-side presses provide a wide choice of tonnage capacity, bed size, stroke, and shut height.

## Factors in Press Selection

Drawing force requirements, die space, and length of stroke are the most important considerations in selecting a press for deep drawing. The condition of the crankshaft, connection bearings, and gibs is also a factor in press selection.

**Drawing Force.** The required drawing force, as well as its variation along the punch stroke, can be calculated from theoretical equations based on plasticity theory or from empirical equations. The maximum drawing force  $F_{d,\max}$  required to form a round cup can be expressed by the following empirical relation:

$$F_{d,\max} = \pi n d t s_u \quad (\text{Eq 6})$$

where  $s_u$  is the tensile strength of the blank material (in pounds per square inch or megapascals),  $d$  is the punch diameter (in inches or millimeters),  $t$  is the sheet thickness (in inches or millimeters), and  $n = s_D/s_u$ , the ratio of drawing stress to tensile strength of the work material. Equation 6 would yield  $F_{d,\max}$  in either pounds or kilonewtons, depending on the other units used.

**Fig. 3** Variation of strain ratio  $r$  with direction in low-carbon steel (top curves) and effect of average strain ratio  $\bar{r}$  on drawability of cylindrical cups (bottom). Each cup represents the deepest cup that can be drawn from material with the indicated  $\bar{r}$ .

**Fig. 4** Defects in deep-drawn cylindrical cups. (a) Flange wrinkling. (b) Wall wrinkling. (c) Tearing. (d) Earing. (e) Surface scratches

The drawing force required to form a round shell can be estimated using Fig. 5. The nomograph shown in Fig. 5 is based on, first, a free draw with sufficient clearance so that there is no ironing and, second, on a maximum reduction of approximately 50% (note also that only English units of measure are used). Figure 5 gives the load required to fracture the cup or the tensile strength of the work metal near the bottom of the shell. An example of its use is the determination of the force required for deep drawing 0.125 in. thick steel stock with a tensile strength of 50,000 psi into a shell 10 in. in diameter:

- Using line 1, connect point 10 on scale 2 to point 0.125 on scale 4.
- Line 1 intersects scale 3 at 4.0, which is the approximate cross-sectional area (in.<sup>2</sup>) of the shell wall.
- Connect this point using line 2 to point 50,000 on scale 1.
- Project a line to the right to intersect scale 5 at 98 tons, which is the required drawing force.

The force required to draw a rectangular cup can be calculated using Eq 7:

$$F_{d,max} = t s_u (2\pi R k_a + L k_b) \quad (\text{Eq 7})$$

where  $R$  is the corner radius of the cup (in inches),  $L$  is the sum of the lengths of straight sections of the sides (in inches),  $k_a$  and  $k_b$  are constants, and the other quantities are as defined in Eq 6. Values for  $k_a$  range from 0.5 for a shallow cup to 2.0 for a cup with a depth five to six times the corner radius;  $k_b$  values range from 0.2 (for easy draw radius, ample clearance, and no blankholder force) to a maximum of 1.0 (for metal clamped too tightly to flow).

When blankholder cylinders are mounted on the main slide of the press, the blankholder force must be added to the calculated drawing force. When a die cushion is used to eject workpieces, the main slide works against this force; therefore, such setups require more drawing force than would be calculated using Eq 6 or 7.

In toggle draw presses, the blankholder force is taken on the rocker shaft bearings in the press

frame, so that the crankshaft bearings sustain only the drawing load. In other types of presses, both the drawing and blankholding loads are on the crankshaft, and allowances are made when computing press capacity. For round work, the allowance for blankholding should be 30 to 40% of the drawing force. For large rectangular work, the drawing force is relatively lower than that for round work, but the blankholding force may be equal to the drawing force. Where stretching is involved and the blank must be gripped tightly around the edge (and a draw bead is not permissible), the blankholding force may be two or three times the drawing force.

**Blank size** governs the size of the blankholder surfaces. Some presses with sufficient force cannot be considered for deep drawing, because the bed size and shut height are inadequate. Blank size is determined by calculating the surface area of the part and then converting this area into a flat blank. For a deep-drawn round cup, the surface area of the cup is converted into a flat blank diameter.

**Draw Depth.** The length of stroke and the force required at the beginning of the working portion of the stroke are both important considerations. Parts that have straight walls can often be drawn through the die cavity and then stripped from the punch and ejected from the bottom of the press. Even under these ideal conditions, the minimum stroke will be equal to the sum of the length of the drawn part, the radius of the draw die, the stock thickness, and the depth of the die to the stripping point, in addition to some clearance for placing the blank in the die.

Workpieces with flanges or tapered walls must be removed from the top of the die. In drawing these workpieces, the minimum press stroke is twice the length of the drawn workpiece, plus clearance for loading the die. In an automatic operation using progressive dies or transfer mechanisms, at least one-half the stroke must be reserved for stock feed, because the tooling must clear the part before feeding begins for the next stroke. For automatic operation, it is common practice to allow a press stroke of four times the length of the drawn workpiece. Therefore, some equipment is not suited to automatic operation, or it is necessary to use manual feed with an automatic unloader, or conversely, because of a shortage of suitable presses.

**Slide Velocity.** When selecting a press, it is also necessary to check slide velocity through the working portion of the stroke (see the section "Effect of Press Speed" in this article).

**Means of Holding the Blank.** Double-action presses with a punch slide and a blankholder slide are preferred for deep drawing. Single-action presses with die cushions (pneumatic or hydraulic) can be used but are less suitable for drawing complex parts. Draw beads are incorporated into the blankholder for drawing parts requiring greater restraint of metal flow than can be obtained by using a plain blankholder or for diverting metal flow into or away from specific areas of the part (see the section "Restraint of Metal Flow" in this article).

Fig. 5 Nomograph used for estimating drawing force based on several parameters. See text for description of use.

**Press Selection versus Availability.** The ideal press equipment for a specific job is often not available. This makes it necessary to design tools and to choose product forms of work metal in accordance with available presses and supplementary equipment. For example, if available presses are not adequate for drawing large workpieces, the manufacturing sequence must be completely changed. It may be necessary to draw two sections and weld them together. In addition, operations that could otherwise be combined, such as blanking, piercing, drawing, and trimming, may have to be performed singly in separate presses.

On the other hand, some manufacturers have placed more than one die in a single press because of the availability of a large press and the shortage of smaller presses. This procedure can cause lower production because all blanks must be positioned before the press can be operated. However, storage of partly formed workpieces and additional handling between press operations are eliminated. Where several small dies are used to reduce overall tool cost, there is economic justification for the use of small-capacity presses. If small presses are not available, it is often more economical to use compound dies. This is particularly true if overall part production is likely to exceed original estimates.

The availability of auxiliary equipment may also influence the type of press and tooling used. For example, if equipment is available for handling coils, plans will be made accordingly. However, if coil-handling equipment is not available and straight lengths of sheet or strip are to be processed, a compatible tooling procedure must be used, even though it may not be the most economical procedure.

## Dies

Dies used for drawing sheet metal are usually one of the following basic types or some modification of these types:

- Single-action dies
- Double-action dies
- Compound dies
- Progressive dies
- Multiple dies with transfer mechanism

Selection of the die depends largely on part size, severity of draw, and quantity of parts to be produced.

**Single-action dies** (Fig. 6a) are the simplest of all drawing dies and have only a punch and a die. A nest or locator is provided to position the blank. The drawn part is pushed through the die and is stripped from the punch by the counterbore in the bottom of the die. The rim of the cup expands slightly to make this possible. Single-action dies can be used only when the forming limit permits cupping without the use of a blankholder.

**Double-action dies** have a blankholder. This permits greater reductions and the drawing of

flanged parts. Figure 6(b) shows a double-action die of the type used in a double-action press. In this design, the die is mounted on the lower shoe, the punch is attached to the inner or punch slide, and the blankholder is attached to the outer slide. The pressure pad is used to hold the blank firmly against the punch nose during the drawing operation and to lift the drawn cup from the die. If a die cushion is not available, springs or air or hydraulic cylinders can be used; however, they are less effective than a die cushion, especially for deep draws.

Figure 6(c) shows an inverted type of double-action die, which is used in single-action presses. In this design, the punch is mounted on the lower shoe; the die on the upper shoe. A die cushion can supply the blankholding force, or springs or air or hydraulic cylinders are incorporated into the die to supply the necessary blankholding force. The drawn cup is removed from the die on the upstroke of the ram, when the pinlike extension of the knockout strikes a stationary knockout bar attached to the press frame.

**Compound Dies.** When the initial cost is warranted by production demands, it is practical to combine several operations in a single die. Blanking and drawing are two operations commonly placed in compound dies. With compound dies, workpieces can be produced several times as fast as by the simple dies shown in Fig. 6.

**Progressive Dies.** The initial cost and length of bed needed for progressive dies usually limit

**Fig. 6** Components of three types of simple dies shown in a setup used for drawing a round cup. See text for discussion.

their application to relatively small workpieces. Figure 7 shows a typical six-station progression for making small shelllike workpieces on a mass-production basis. However, larger parts, such as liners for automobile headlights, have been drawn in progressive dies.

The total number of parts to be produced and the production rate often determine whether or not a progressive die will be used when two or more operations are required. There are, however, some practical considerations that may rule against a progressive die, regardless of quantity:

- The workpiece must remain attached to the scrap skeleton until the final station, without hindering the drawing operations.
- Drawing operations must be completed before the final station is reached.
- In deep drawing, it is sometimes difficult to move the workpiece to the next station.
- If the draw is relatively deep, stripping is often a problem.
- The length of press stroke must be more than twice the depth of draw.

Assuming that a progressive die can be used to make acceptable drawn parts, cost per piece is usually the final consideration. Progressive-die drawing is generally considered to be economical if savings in material and labor can pay for the die in 1 year. Ordinarily, the savings achieved by the use of a progressive die results from decreased labor.

**Multiple dies,** in conjunction with transfer mechanisms, are often used instead of progressive dies for the mass production of larger parts. Multiple dies and transfer mechanisms are practical for a wider range of workpiece sizes than progressive dies are. Although the eyelet-type transfer method is the most widely used for making parts less than 25 mm (1 in.) in diameter, transfer dies are practical for much larger workpieces. The seven-station operation for making the 165 mm (6.5 in.) outside diameter cylindrical shell shown in Fig. 8 represents a typical sequence for the transfer-die method. The workpiece is mechanically transferred from one die to the next. One advantage of the transfer-die method, as opposed to the progressive-die method, is the greater flexibility permitted in processing procedure, mainly because in transfer dies the workpiece does not remain attached to the scrap skeleton during forming. Because of

**Fig. 7** Production of a small ferrule in a six-station progressive die. Dimensions given in inches

this, precut blanks can be drawn by the transfer method.

Preforms can also be used as blanks. For example, oil pans for automobiles are blanked and partly drawn in a compound die and then finish formed, pierced, and trimmed by the transfer method. Dies for producing a given part usually cost more for the transfer-die method than for a separate-die operation but approximately the same as for a progressive-die operation. The cost of adapting the transfer unit to the part is not included in the die cost. Similarly, the production rate for the transfer method is usually greater than that for a single-die operation but 10 to 25% less than that for drawing in a progressive die. Many parts can be produced equally well by all of these methods. Under these conditions, tool cost, rate of production, and total quantity of parts to be drawn determine the choice of procedure.

**Die and Punch Materials.** The selection of material for dies and punches for drawing sheet metal depends on work metal composition, workpiece size, severity of the draw, quantity of parts to be drawn, and tolerances and surface finish specified for the drawn workpieces. To meet the wide range of requirements, punch and die materials ranging from polyester, epoxy, phenolic, or nylon resins to highly alloyed tool steels with nitrided surfaces, and even carbide, are used. Detailed information on tool materials is available in the articles "Selection of Materials for Press-Forming Dies" and "Selection of Materials for Deep-Drawing Dies" in this Volume.

## Effects of Process Variables in Deep Drawing

The process parameters that affect the success or failure of a deep-drawing operation include punch and die radii, punch-to-die clearance, press speed, lubrication, and type of restraint of metal flow used (if any). Material variables, such as sheet thickness and anisotropy, also affect deep drawing. These are discussed in the section "Effects of Material Variables on Deep Drawing" in this article.

### Effect of Punch and Die Radii

As the blank is struck by the punch at the start of drawing, it is wrapped around the punch and die radii; the stress and strain that develop in the workpiece are similar to those developed in bending, with an added stretching component. The bends, once formed, have the radii of the punch and die corners. The bend over the punch is stationary with reference to both punch and shell wall. The bend over the die radius, however, is continuously displaced with reference to both the punch radius and the blank, and it also undergoes a gradual thickening as the shell is drawn. The force required to draw the shell at the

intermediate position has a minimum of three components:

- The force required for bending and unbending the metal flowing from the flange into the sidewall
- The force required for overcoming the frictional resistance of the metal passing under the blankholder and over the die radius
- The force required for circumferential compression and radial stretching of the metal in the flange

Because of the variation in metal volume and in resistance to metal flow, the punch force increases rapidly, passes through a maximum, and gradually decreases to zero as the edges of the flange approach and enter the die opening and pass into the shell wall. With the cup diameter remaining constant, the maximum press load and the length of stroke required to draw the cup depend on the size of the blank. The punch force-stroke relations for drawing blanks of various diameters from brass sheet 1.5 mm (0.060 in.) thick, using a 50 mm (2 in.) diameter punch, are shown in Fig. 9.

Under the conditions shown in Fig. 9, during cupping, the shell bottom is subjected to tensile stress in all directions, while the lower portions

**Fig. 8** Seven-station drawing and piercing of a cylindrical part in a multiple die and transfer mechanism. Dimensions given in inches

**Fig. 9** Force-stroke relations for drawing blanks of various diameters from 1.5 mm (0.060 in.) thick alloy C27400 (yellow brass, 63%) sheet using a 50 mm (2 in.) diameter punch. Numbers indicate blank diameter in millimeters.

of the shell wall, particularly the radiused portion connecting the bottom with the wall, are primarily subjected to longitudinal tension. The stress in the metal being drawn into the shell wall consists of combined compressive and tensile stresses. Separation of the shell bottom from the wall is likely if a reduction is made that requires a force greater than the strength of the shell wall near the bottom (Fig. 9).

The punch and die radii and percentage of reduction determine the load at which the bottom of the shell is torn out. Drawing is promoted by increasing punch and die radii. For a given drawing condition, the punch force needed to move the metal into the die decreases as the die radius increases, as shown in Fig. 10.

The reduction of drawing force in a double-action die by modification of the effective die radius can be accomplished in two convenient ways, as shown in Fig. 11. In the conical lead-in die (Fig. 11a), the cutout is effective in reducing

**Fig. 10** Effect of die radius on punch force required for cupping various diameters of 1 mm (0.040 in.) thick alloy C27400 (yellow brass, 63%) blanks using a 30.5 mm (1.2 in.) diameter punch with a nose radius of 0.61 mm (0.024 in.). Numbers indicate blank diameter in millimeters.

**Fig. 11** Two ways of reducing the required drawing forces. (a) Conical lead-in die. (b) Conical blankholder. See text for details.

frictional loads by removal of the portions of the die surface that are usually heavily loaded and increase friction. In Fig. 11(b), the sheet metal is formed into a conical shape before appreciable drawing begins. This has the effect of reducing the area of contact over the die radius by an amount proportional to  $\alpha/90^\circ$  (where  $\alpha$  is the angle to declination of the hold-down surface to the horizontal, as shown in Fig. 11b).

If the punch nose radius can be increased from one to five times metal thickness, the load in the sidewall of the shell will decrease so that the reduction in blank diameter will increase from 35% to approximately 50% (for steel). The shell can therefore be drawn deeper before the sidewall tears. If the shell bottom radius is less than four times the sheet thickness, it is usually desirable to form it with a larger-radius punch and then to restrike to develop the specified radius. This will minimize bottom failures. However, the bottom corner radius usually cannot be increased beyond ten times the sheet thickness without the likelihood of wrinkling. The metal in dome-shaped parts is likely to pucker in the unconfined area between the punch nose and die radius. High blankholding forces or draw beads are often used to induce combined stretching and drawing of the metal when forming dome shapes.

The deep drawing of stainless steel or high-strength alloy boxes with sides longer than 50 times stock thickness may result in a stability problem called oil canning. The deflection of the sides by snap action can be eliminated by drawing the part in two operations with slightly different punches and an intermediate anneal. The first-draw punch will have a larger nose radius than the second; therefore, in the second drawing operation, the metal can be stretched to eliminate the oil-canning effect. Stretching of the metal in parts with long sidewalls can be improved by gradually increasing the punch nose radius from the corner toward the center. A constant nose radius is used on the second-draw punch.

### Effect of Punch-to-Die Clearance

The selection of punch-to-die clearance depends on the requirements of the drawn part and on the work metal. Because there is a decrease and then a gradual increase in the thickness of the metal as it is drawn over the die radius, clearance per side of 7 to 15% greater than stock thickness (1.07 to 1.15 $t$ ) helps prevent burnishing of the sidewall and punching out of the cup bottom.

The drawing force is minimal when the clearance per side is 15 to 20% greater than stock thickness (1.15 to 1.20 $t$ ) and the cupped portions of the part are not in contact with the walls of the punch and die. The force increases as the clearance decreases, and a secondary peak occurs on the force-stroke curve where the metal thickness is slightly greater than the clearance and where ironing starts.

Redrawing operations require greater clearance, in relation to blank thickness, than the first draw in order to compensate for the increase in metal thickness during cupping. A sizing redraw is used where the diameter or wall thickness is important or where it is necessary to improve surface finish to reduce finishing costs. The clearance used is less than that for the first draw.

Table 1 lists clearances for cupping, redrawing, and sizing draws of cylindrical parts from metal of various thicknesses. As the tensile strength of the stock decreases, the clearance must be increased.

Clearance between the punch and die for a rectangular shell, at the sidewalls and ends, is approximately the same as, or slightly less than, that for a circular shell. Clearance at the corners may be as much as 50% greater than stock thickness to avoid ironing in these areas and to increase drawability.

### Restraint of Metal Flow

Even in the simplest drawing operation, as shown in Fig. 6(a), the thickness of the work metal and the die radius offer some restraint to the flow of metal into the die. For drawing all but the simplest of shapes, some added restraint is generally required in order to control the flow of metal. This additional restraint is usually obtained by the use of a blankholder, as illustrated in Fig. 6(b) and (c). The purpose of the blankholder is to suppress wrinkling and puckering and to control the flow of the work metal into the die.

**Drawing without a Blankholder.** A blank is not susceptible to wrinkling, and a blankholder need not be used, if the ratio of supported length to sheet thickness is within certain limits. In Fig. 12, the supported length ( $l$ ) is the length from the edge of the blank to the die cavity (point of tangency). The sheet thickness is denoted as  $t$ . The  $l/t$  ratio is influenced little by other geometrical conditions, and it differs little for the various metals commonly drawn. When the  $l/t$  ratio does not exceed 3 to 1, a cup can be drawn from annealed brass, aluminum (to half-hard), and low-carbon steel without a blankholder. For

slightly harder work metals, such as hard copper or half-hard brass, this ratio should not exceed 2.5 to 1.

An elliptical or conical die opening, such as that shown in Fig. 11(a), can be used where the die radius required to draw the part reduces the length of the blank-supporting surface to less than three times stock thickness. The distance between the die opening and the punch should not exceed ten times stock thickness.

A  $30^\circ$  elliptical radius derived from a circle created by a given draw radius increases the strain on the metal being drawn by 4.2%, but it decreases the metal out of control by 47% of the length of the original draw radius. This shape has been helpful in the drawing of tapered shells from a flat blank. For these draws, it is desirable to increase the strain slightly to prevent puckers and to reduce the metal out of control for the same reason.

A  $45^\circ$  elliptical radius derived as stated previously reduces the strain on the metal being drawn by 1.03% and reduces the metal out of control by 33% of the length of the original draw radius. The  $45^\circ$  ellipse is useful only when a large radius will draw the part, but produces wrinkles. A smaller radius will not permit the draw.

A  $60^\circ$  elliptical radius does not measurably reduce drawing strain and accounts for only a 9% reduction of metal out of control. Its use on draw dies is not economically feasible when the small gains derived are considered in relation to the cost of producing the contour. The drawing of thick metal without a blankholder is frequently done when the blank diameter is no greater than 20 times stock thickness.

**Blankholders.** A blankholder, or binder, is used to control metal flow into the die cavity and to prevent wrinkles from forming in the flange of a deep-drawn part. The formation of wrinkles interferes with, or prevents, the compressive action that rearranges the metal from flange to sidewall. Much greater reductions are possible when a blankholder is used.

Blankholders can be used in double- and single-action presses. In a double-action press, the blankholder advances slightly ahead of the punch and dwells at the bottom of its stroke throughout the drawing phase of the punch cycle. The blankholder dwell usually extends to a point on the punch upstroke at which positive stripping of the shell is ensured. By using a die cushion and an inverted die, similar action can be obtained in a single-action press. A die cushion in a double-action press supports the blank and holds it

**Table 1** Punch-to-die clearance for drawing operations

Metal thickness, $t$		Clearance-to-metal-thickness relationship for:		
mm	in.	Cupping	Redrawing	Sizing draws
Up to 0.38	Up to 0.015	1.07–1.09 $t$	1.08–1.10 $t$	1.04–1.05 $t$
0.41–1.27	0.016–0.050	1.08–1.10 $t$	1.09–1.12 $t$	1.05–1.06 $t$
1.29–3.18	0.051–0.125	1.10–1.12 $t$	1.12–1.14 $t$	1.07–1.09 $t$
3.2 and up	0.126 and up	1.12–1.14 $t$	1.15–1.20 $t$	1.08–1.10 $t$

**Fig. 12** The ratio of supported length  $l$  to sheet thickness  $t$  determines whether or not a blankholder is required for deep drawing.

against the punch during the drawing operation; it then lifts the finished part out of the die.

A blankholder must allow the work metal to thicken as the edge of the blank moves inward toward the working edge of the die. The amount of thickening is expressed by:

$$\frac{t_1}{t} = \sqrt{\frac{D}{D_1}} \quad (\text{Eq 8})$$

where  $t$  is the blank thickness,  $t_1$  is the thickness of the flange at any instant during the drawing operation,  $D$  is the blank diameter, and  $D_1$  is the diameter of the flange at any instant during the drawing operation (or the mean diameter of the workpiece without the flange). As the metal flows, paths of least resistance are taken; therefore, the actual value of  $t_1$  will be less than that calculated from the formula.

**Types of Blankholders.** Blankholders can be flat, or they may have a combination of fixed drawbeads and constant blankholder displacements. In flat binders, restraining forces in the drawn sheet are provided by friction between the binder plates and the sheet metal. In fixed drawbead binders, restraining forces result from a combination of plastic deformation and friction. The simplest type of blankholder is fixed to the die block and has a flat hold-down surface, as shown in Fig. 13(a). A disadvantage of this type of blankholder is that maintenance of the optimal gap between the die surface and the flat hold-down surface requires careful adjustment. As shown in Fig. 13, the blankholder does not quite contact the work metal as drawing begins; restraint begins and increases as the flange portion thickens. A gap that is either too small or too large increases force and reduces drawability. For optimal results, the gap should be slightly smaller than the flange thickness, allowing 50 to 75% of the final thickening before the work metal contacts the blankholder.

The flat controlled-pressure blankholder shown in Fig. 13(b) is generally preferred in production operations because it can be adjusted to a predetermined and closely controlled value by hydraulic or pneumatic pressure. Springs, unless extremely long, are not suitable for supplying pressure to a blankholder during deep drawing, because the force exerted by a spring increases rapidly as it is compressed. The force on hydraulic or pneumatic die cushions will increase approximately 20% when compressed the full stroke length. Some hydraulic systems have pressure control valves that supply a more nearly constant pressure during the entire stroke.

The fixed-type blankholder (Fig. 13a) draws a cup without a flange and ejects it through the bottom of the die. The blankholder shown in Fig. 6(b) and (c) and in Fig. 13(b) can be used for drawing a cup with or without a flange. Cups without a flange can be pushed through the die if a pressure pad is not needed to support the blank.

**Flexible Blankholder.** Conventional stamping with rigid binders does not allow local control of sheet metal flow into the die cavity, as shown in Fig. 14. This produces a forming

system with limited application and leads to an elaborate and costly die tryout process to produce a product. New tooling concepts and an advanced binder control system were developed and implemented in Germany. The new development produces flexible binders with individually controlled hydraulic cylinders, as shown in Fig. 15. Individual control of local binder areas allows the right amount of metal to flow into the die cavity. Unlike rigid binders, a flexible binder produces the right amount of elastic deformation in the binder area, and this produces the necessary friction condition for metal flow.

Fig. 13 Setups showing the use of two types of blankholders. See text for details.

Fig. 14 Schematic of a rigid sheet metal forming system

Fig. 15 Flexible binder with individually controlled hydraulic cylinders

The cone-shaped segments localize the applied pressure in a specific area without influencing the pressure in adjacent areas. Trials on an automotive front fender were conducted using a ten-point cushion system in a hydraulic press. Results from the trials showed that flexible binder technology improves the quality of fenders by allowing the manipulation of pressure settings in binder areas that control metal flow to the defect location. The effect of binder load control on wrinkling behavior at the nose of the fender is shown in Fig. 16 and 17. Figure 16 shows wrinkles obtained when nonoptimized pin forces

Fig. 16 Wrinkles obtained using nonoptimized pin forces

Fig. 17 Reduction in wrinkles after optimizing pin forces

were used. Figure 17 shows that less wrinkles were obtained when the pin forces in the binder area are optimized. Flexible binder control technology is currently being used to successfully deep draw stainless steel double sinks.

**Blankholder Force.** Compressive forces on the metal in the area beyond the edge of the die cause the work metal to buckle. If this buckled or wrinkled metal is pulled into the die during the drawing operation, it will increase the strain in the area of the punch nose to the point at which the work metal would fracture soon after the beginning of the draw. Blankholder force is used to prevent this buckling and subsequent failure. The amount of blankholder force required is usually approximately one-third that required for drawing. Thickness of the work metal must also be considered when simple shapes are being drawn; the thinner the work metal, the more blankholder force that is required.

There are no absolute rules for calculating blankholder force for a given drawing operation; most blankholder force values are found empirically. Blankholder force should be just sufficient to prevent wrinkling, and it depends on draw reduction, work metal thickness and properties, the type of lubrication used, and other factors. For a particular application, blankholder force is best determined experimentally.

**Draw beads** help prevent wrinkles and control the flow of metal in the drawing process. The use of draw beads increases the cost of tools, product development, and tool maintenance. However, they are often the only means of controlling metal flow in the drawing of odd shapes. Draw beads are ordinarily used for the first draw only; therefore, production rates are the same as when conventional blankholders are used. For low production, draw beads are often made by laying a weld bead on the die after the optimal location has been determined.

Restraint of the metal flow, to the extreme of locking the flange of the blank to prevent motion, is needed for some draws. A deep shell with sloping walls can be made by drawing, followed by several redraws. This results in a stepped workpiece. The final sizing draw is a stretching operation that is done with the flange secured by a locking bead in the blankholder. This kind of blankholder is also used in making shallow drawn panels. Additional information on the design and use of draw beads is available in the article "Forming of Carbon Steels" in this Volume.

### Effect of Press Speed

Drawing speed is usually expressed in meters per minute (m/min) or linear feet per minute (ft/min). Under ideal conditions, press speeds as high as 23 m/min (75 ft/min) are used for the deep drawing of low-carbon steel. However, 6 to 17 m/min (20 to 55 ft/min) is the usual range—up to 17 m/min (55 ft/min) for single-action presses and 11 to 15 m/min (35 to 50 ft/min)

for double-action presses. Ideal conditions include:

- Use of a drawing-quality work metal
- Symmetrical workpieces of relatively mild severity
- Adequate lubrication
- Precision carbide tools
- Carefully controlled blankholding pressure
- Presses that are maintained to a high level of accuracy

When one or more of the aforementioned conditions is less than ideal, some reduction in press speed is required. If all, or nearly all, are substantially less than ideal, press speed may have to be reduced to 6 m/min (20 ft/min). When the operation includes ironing, the drawing speed is usually reduced to approximately 7.5 m/min (25 ft/min) regardless of other factors.

The punch speed in hydraulic presses is relatively constant throughout the stroke. In mechanical presses, punch speed is that at midstroke, because the velocity changes in a characteristic manner throughout the drawing stroke from maximum velocity to zero. The only adjustment in speed that can be made is to decrease flywheel speed or to use a press with a shorter stroke that operates at the same number of strokes per minute. This proportionately decreases maximum punch speed. Speed is of greater significance in drawing stainless steels and heat-resistant alloys than in drawing softer, more ductile metals. Excessive press speeds have caused cracking and excessive wall thinning in drawing these stronger, less ductile metals. At high speeds, the metal thins because it cannot react to the impact speed of the punch. Reducing the speed reduces the stretching and gives the metal enough time to flow plastically. Nominal speeds for drawing various metals are given in Table 2.

### Effect of Lubrication

When two metals are in sliding contact under pressure, as with the dies and the work metal in drawing, galling (pressure welding) of the tools and the work metal is likely. When extreme galling occurs, drawing force increases and becomes unevenly distributed, causing fracture of the workpiece.

The likelihood of pressure welding depends on the amount of force and the work metal composition. Some work metals are more "sticky" than others. For example, austenitic stainless steel is more likely to adhere to steel tools than low-carbon steel is.

Lubricants are used in most drawing operations. They range from ordinary machine oil to pigmented compounds.

Selection of lubricant is primarily based on the ability to prevent galling, wrinkling, or tearing during deep drawing. It is also influenced by ease of application and removal, corrosivity, and other factors, as described in the article

"Selection and Use of Lubricants in Forming of Sheet Metal" in this Volume.

If a lubricant cannot be applied uniformly by ordinary shop methods, its purpose is defeated, regardless of its ability to prevent pressure welding. In general, as the effectiveness of a lubricant increases, the difficulty of removing it also increases. For example, grease or oil can be easily removed, but special procedures (frequently including some hand scrubbing) are required for removing lubricants that contain zinc oxide, lithopone, white lead, molybdenum disulfide, or graphite.

A lubricant is sometimes too corrosive for use on certain metals. For example, copper alloys are susceptible to staining by lubricants that contain large amounts of sulfur or chlorine compounds. Lubricants containing lead or zinc compounds are not recommended for drawing stainless steel or heat-resistant alloys, because the compounds, if not thoroughly removed, can cause intergranular attack when the workpieces are heat treated or placed in high-temperature service. Suitable safety precautions are necessary with toxic or flammable lubricants.

Some metals, such as magnesium and titanium, are drawn at elevated temperature, which complicates selection of the lubricant. Most oil-base and soap-base lubricants can be successfully used to 120 °C (250 °F), but above this temperature, the choice narrows rapidly. Some special soap-base lubricants can be used on work metals to 230 °C (450 °F). Molybdenum disulfide and graphite can be used at higher temperatures.

Any lubricant must remain stable, without becoming rancid, when stored for a period of several months at various temperatures. The cost of application and removal of the lubricant, as well as its initial cost, must be considered because all of these items can add substantially to the cost of the drawn workpieces.

In some plants, when a new application is started, a heavily pigmented drawing lubricant is used, regardless of the difficulty of applying and removing it. Lubricant is then downgraded as much as possible to simplify the operation and to reduce costs. In other plants, the reverse of this practice is used; that is, a simple lubricant, such as machine oil, is used at first, and lubricant is then upgraded when necessary.

The difficulty of removing drawing lubricants is an important consideration in production operations. In a number of applications, changes in drawing techniques (such as increasing the

**Table 2 Typical drawing speeds for various materials**

Material	Drawing speed	
	m/min	ft/min
Aluminum	45.7–53.3	150–175
Brass	53.3–61	175–200
Copper	38.1–45.7	125–150
Steel	5.5–15.2	18–50
Stainless steel	9.1–12.2	30–40
Zinc	38.1–45.7	125–150

number of draws) or in workpiece design (larger radii, for example) have been made solely to permit the use of an easier-to-remove drawing lubricant. Methods of removing lubricants are discussed in the section “Cleaning of Workpieces” in this article.

Typical lubricants used in drawing steel are given in Table 3 according to severity of draw or the percentage of reduction from blank to cup diameter. Zinc phosphate conversion coating of the steel to be drawn is helpful for any drawing operation, and the importance of phosphate coating increases as the severity of the draw increases. Methods of application and other details on the use of phosphate conversion coatings are discussed in the article “Phosphate Coatings” in *Surface Engineering*, Volume 5, *ASM Handbook*, 1994.

## Materials for Deep Drawing

Sheet steels and other sheet metals with higher strengths and better formability have recently become available. Developments such as vacuum processing and inclusion shape control have been especially beneficial in increasing the drawability of steels. Other metals and alloys that can be deep drawn include aluminum and aluminum alloys, copper and alloys, some stainless steels, and titanium.

**Low-carbon sheet steels** are the materials that are most commonly deep drawn and are commonly used, for example, in the automotive industry. Materials such as 1006 and 1008 steel have typical yield strengths in the range of 170 to 240 MPa (25 to 35 ksi) and elongations of 35 to 45% in 50 mm (2 in.). These materials have excellent formability and are available cold or hot finished in various quality levels and a wide range of thicknesses. Table 4 lists mechanical properties of the various qualities of carbon steel sheet.

Other low-carbon steels that are commonly deep drawn are grades 1010 and 1012. These materials are slightly stronger than 1006 and 1008 and are slightly less formable. They are often specified when drawing is not severe and strength of the finished part is of some concern. Grain size affects the drawability of these materials, and it may affect the selection of a grade. Grain sizes of ASTM 5 or coarser may result in excessive surface roughness as well as reduced drawability.

Surface finish also influences drawability. The dull finish normally supplied on drawing steels is designed to hold lubricants and to improve drawability. Brighter finishes may be required if, for example, parts are to be electroplated.

## Effects of Material Variables on Deep Drawing

**Anisotropy.** As mentioned earlier in this article, there are two types of anisotropy that must be considered: planar anisotropy, in which properties vary in the plane of the sheet, and

normal anisotropy, in which the properties of the material in the thickness direction differ from those in the plane of the sheet.

Planar anisotropy (variations in normal anisotropy in the plane of the sheet) causes undesirable earing of the work material during drawing.

**Table 3 Lubricants commonly used for the drawing of low-carbon steel**

Severity is indicated by the percentage of reduction in diameter in drawing a cylindrical shell.

Type or composition of lubricant	Ease of removal by:		Protection against rusting
	Water-base cleaners	Degreasers or solvents	
<b>Water-base lubricants</b>			
Low severity (10% or less)			
Water emulsion of 5–20% general-purpose soluble oil or wax	Very good	Good	Fair
Moderate severity (11–20%)			
Water solution of 5–20% soap	Very good	Very poor	Fair
Water emulsion of heavy-duty soluble oil (contains sulfurized or chlorinated additives)	Very good	Good	Fair
High severity (21–40%)			
Soap-fat paste, diluted with water (may contain wax)	Fair	Poor	Fair
Water emulsion of heavy-duty soluble oil (contains a high concentration of sulfurized or chlorinated additives)	Very good	Good	Fair to poor
Maximum severity (> 40%)			
Pigmented soap-fat paste, diluted with water	Poor	Very poor	Good
Dry soap or wax (applied from water solution or dispersion); may contain soluble filler such as borax	Good	Very poor	Good
<b>Oil-base lubricants</b>			
Low severity (10% or less)			
Mill oil, residual	Good	Very good	Fair
Mineral oil	Good	Very good	Fair
Vanishing oil	Removal not required		...
Moderate severity (11–20%)			
Mineral oil plus 10–30% fatty oil	Good	Very good	Fair
Mineral oil plus 2–20% sulfurized or chlorinated oil (extreme-pressure oil)	Good to fair	Good	Fair to poor
High severity (21–40%)			
Fatty oil	Fair	Fair	Fair
Mineral oil plus 5–50% of:			
(a) Nonemulsifiable chlorinated oil	Poor	Good	Very poor
(b) Emulsifiable chlorinated oil	Good	Good	Very poor
Concentrated phosphated oil	Fair	Fair	Fair
Maximum severity (> 40%)			
Blend of pigmented soap-fat paste with mineral oil	Poor	Poor	Fair
Concentrated sulfochlorinated oil (may contain some fatty oil):			
(a) Nonemulsifiable	Very poor	Fair	Poor
(b) Emulsifiable	Good	Fair	Poor
Concentrated chlorinated oil:			
(a) Nonemulsifiable	Very poor	Fair	Very poor
(b) Emulsifiable	Good	Fair	Very poor

**Table 4 Typical mechanical properties of low-carbon sheet steels**

Quality level	Tensile strength		Yield strength		Elongation, % in 50 mm (2 in.)	Plastic-strain ratio, $r$	Strain-hardening exponent, $n$	Hardness, HRB
	MPa	ksi	MPa	ksi				
Hot rolled								
Commercial quality	358	52	234	34	35	1.0	0.18	58
Drawing quality	345	50	220	32	39	1.0	0.19	52
Drawing quality, aluminum killed	358	52	234	34	38	1.0	0.19	54
Cold rolled, box annealed								
Commercial quality	331	48	234	34	36	1.2	0.20	50
Drawing quality	317	46	207	30	40	1.2	0.21	42
Drawing quality, aluminum killed	303	44	193	28	42	1.5	0.22	42
Interstitial-free	310	45	179	26	45	2.0	0.23	44

Between the ears of the cup are valleys in which the material has thickened under compressive hoop stress rather than elongating under radial tensile stress. This thicker metal sometimes forces the die open against the blankholder pressure, allowing the metal in the relatively thin areas near the ears to wrinkle. Die design, draw reduction, and type of lubricant used all affect earing (see the section "Effects of Process Variables in Deep Drawing" in this article).

**Sheet Thickness.** In deep drawing, the pressure on the dies increases proportionally to the square of sheet thickness. The pressure involved is concentrated on the draw radius, and increasing sheet thickness will localize wear in this area without similar effect on other surfaces of the die. Thick stock has fewer tendencies to wrinkle than thin stock. As a result, blankholder pressures used for the drawing of thick sheet may be no greater, and may even be less, than those used for thinner blanks.

## Redrawing Operations

If the shape change required by the part design is too severe (the drawing ratio is too high), a single drawing operation may not produce complete forming of the part, and more than one drawing step may be required.

**Direct Redrawing.** In direct redrawing in a single-action die, the drawn cup is slipped over the punch and is loaded in the die, as shown in Fig. 18. At first, the bottom of the cup is wrapped around the punch nose without reducing the diameter of the cylindrical section. The sidewall section then enters the die and is gradually reduced to its final diameter. Metal flow takes place as the cup is drawn into the die so that the wall of the redrawn shell is parallel to, and deeper than, the wall of the cup at the start of the redraw. At the beginning of redrawing, the cup must be supported and guided by a recess in the die or by a blankholder to prevent it from tipping, because tipping would result in an uneven shell.

**Fig. 18** Direct and reverse redrawing in single-action and double-action dies

In a single-action redraw, the metal must be thick enough to withstand the compressive forces set up in reducing the cup diameter without wrinkling. Wrinkling can be prevented by the use of an internal blankholder and a double-action press (upper right, Fig. 18), which usually permits a shell to be formed in fewer operations than by single-action drawing without the use of a blankholder.

Internal blankholders (Fig. 19) are slip fitted into drawn shells to provide support and to prevent wrinkling during direct redrawing. The blankholder presses on the drawn shell at the working edge of the die before the punch contacts the bottom of the shell and begins the redraw. It dwells against the shell as the metal is drawn into the die by the punch, preventing wrinkles.

The bottom of the cup to be redrawn can be tapered (Fig. 19a) or radiused (Fig. 19b), with the tip of the blankholder and the mouth of the die designed accordingly. An angle of  $30^\circ$  is used for metal thinner than 0.8 mm ( $1/32$  in.), and  $45^\circ$  is used for thicker work metal. A modification of the aforementioned is a blankholder fitted against an S-curve die (Fig. 19b). The main disadvantage of an S-curve die is that it is more expensive to make and maintain. Near the bottom of a redrawn shell, there is usually a narrow ring, caused by the bottom radius of the preceding shell, which is thinner and harder than the adjacent metal. Redrawing may be required for reasons other than the severity of the drawn shape, for example, to prevent thinning and bulging.

Redrawing can also be done in a progressive die while the part is still attached to the strip. Where space permits the extra stations, the amount of work done in each station will be less than that done in a single die. This reduces the severity of the draw and promotes high-speed operation.

**Reverse Redrawing.** In reverse redrawing, the cupped workpiece is placed over a reversing

**Fig. 19** Setups using internal blankholders for restraint of work metal in redrawing shells. See text for details.

ring and redrawn in the direction opposite to that used for drawing the initial cup. As shown in the two lower views in Fig. 18, reverse redrawing can be done with or without a blankholder. The blankholder serves the same purposes as in direct redrawing.

The advantages of reverse redrawing as compared with direct redrawing include:

- Drawing and redrawing can be accomplished in one stroke of a triple-action hydraulic press, or of a double-action mechanical press with a die cushion, which can eliminate the need for a second press.
- Greater reductions per redraw are possible with reverse redrawing.
- One or more intermediate annealing operations can often be eliminated by using the reverse technique.
- Better distribution of metal can be obtained in a complex shape.

In borderline applications, annealing is required between redraws in direct redrawing but is not needed in reverse redrawing.

The disadvantages of reverse redrawing are:

- The technique is not practical for work metal thicker than 6.4 mm ( $1/4$  in.).
- Reverse redrawing requires a longer stroke than direct redrawing.

Usually, metals that can be direct redrawn can be reverse redrawn. All of the carbon and low-alloy steels, austenitic and ferritic stainless steels, aluminum alloys, and copper alloys can be reverse redrawn.

Reverse redrawing requires more closely controlled processing than direct redrawing does. This control must begin with the blanks, which should be free from nicks and scratches, especially at the edges.

The restraint in reverse redrawing must be uniform and low. For low friction, polished dies and effective lubrication of the work are needed. Friction is also affected by hold-down pressure and by the shape of the reversing ring. Radii of tools should be as large as practical, ten times the thickness of the work metal if possible. Reverse redrawing can be done in a progressive die as well as in single-stage dies if the operations are divided to distribute the work and to reduce the severity of each stage.

**Tooling for Redrawing.** Tooling for redrawing depends mainly on the number of parts to be redrawn and on available equipment. In continuous high production, a complete die is used for each redraw; the workpieces are conveyed from press to press until completed. In low or medium production, it is common practice to use a die with replaceable draw rings and punches. A die of this type used for three redrawing operations is shown in Fig. 20; the three redraws were made by changing to successively smaller draw rings and punches. The cup was drawn in a compound blank-and-draw die from a blank 1.7 mm (0.067 in.) thick and 170 mm ( $6\frac{3}{4}$  in.) in diameter.

## Ironing

Ironing is an operation used to increase the length of a tube or cup by reducing wall thickness and outside diameter, while the inner diameter remains unchanged. Wall thickness is reduced by pulling tubes or shells through tight dies. The process of ironing is similar to tube drawing with a moving mandrel, whereby drawing is carried out by using several drawing dies located in tandem. In a typical application, a relatively thick-wall cup is first produced by extrusion or deep drawing. The wall thickness of this cup is then reduced by tandem ironing with a cylindrical punch, while the internal diameter remains unchanged. Hot and cold ironing produce parts with good dimensional accuracy while maintaining or improving concentricity. A very common application of ironing is the production of beverage cans by tandem drawing of steel or aluminum.

Ironing is done to:

- Obtain a wall that is thin compared with the shell bottom
- Obtain a uniform wall
- Obtain a tapered wall (as in cartridge cases), or merely to correct the natural wall thickening that occurs toward the top edge of a drawn shell

The theoretical maximum reduction in wall thickness per operation due to ironing is approximately 50%. In such a case, the cross-sectional area of the (unstrained) metal before ironing is approximately twice the cross-sectional area after ironing. Therefore, the area that is being worked in compression and that must yield is approximately equal to the strain-hardened area that is in tension and that must not yield. This would indicate that the practical limit should apparently be kept below 50%, although slightly higher reductions may be possible.

The chart in Fig. 21 (Ref 1) is arranged to show approximately the natural change in thickness

**Fig. 20** Die in which draw rings and punches can be replaced for producing three successive redraws. Dimensions given in inches

accompanying a change in diameter. The results apply to the upper edges of drawn shells, because the wall thickness tapers from a maximum at that point to a minimum at the bottom corner, where it may be as much as 10 or 15% less than the original metal thickness. Even at the top edge, the metal thickness is likely to be a little less than the theoretical thickness given by the chart because of the thinning effect of bending over the drawing edge. A sharper radius or a deeper draw increases this thinning effect.

An example is indicated by dashed lines in Fig. 21. It is noted that this is based on a draw with sufficient clearance between the punch and die so that there will be no ironing. If the clearance between punch and die is made equal to the metal thickness (0.0625 in., or 1.6 mm, in the example), there will be an ironing load (added to the drawing load) that is sufficient to reduce the wall thickness by 0.45 mm (0.018 in., or 0.0805 in. - 0.0625 in. = 0.018 in.). If a parallel wall is desired, it will be necessary to iron

**Fig. 21** Chart for determining approximate changes in thickness from changes in outer diameter due to ironing. Read the chart from left to right. (1) Draw a line between the original shell or blank diameter and the final diameter (on the two inner scales) to obtain the maximum percent reduction or expansion on the center scale. (2) Draw a second line through this point, starting from the original metal thickness on the left-hand scale, to indicate the approximate maximum wall thickness at the upper edge of the final shell. Source: Ref 1

down to the thickness of the thinnest part of the wall, which is appreciably less than the original metal thickness, depending on the sharpness of corner radii and the severity of reductions.

The chart in Fig. 22 offers a convenient means of approximating the pressure required in ironing. Referring to the example shown in dashed lines, note that the two inner scales are used first to establish the pivot point on the center scale. Thus, a shell ironed to a finished diameter of 100 mm (4 in.), with a displacement of 0.25 mm (0.010 in.) of the total metal thickness, will require an ironing pressure of approximately 3.8 tons, assuming that the metal is spheroidized steel moderately strain hardened and therefore offering a compressive resistance of approximately 620 MPa (90 ksi). This must be added, of course, to the drawing or redrawing load figured separately. The formula is  $P = 1.2 \pi d \cdot i \cdot S$ , where  $P$  is the approximate required maximum pressure (in tons),  $d$  is the outside diameter (in inches) after ironing,  $i$  is the reduction in wall thickness (in inches), and  $S$  is the compressive resistance (in psi) of the metal under existing

conditions of strain hardening. There is included a 20% allowance for surface friction in addition to the work of coining. This is an arbitrary figure that should cover well-polished dies and suitable lubrication. Lack of lubricant, toolmark rings on the dies, or surface pickup will increase the friction load considerably.

If the wall of a shell is ironed thinner by the same amount for the entire length of the shell, then the work done is approximately the product of the length of the shell or of the ironed surface and the pressure required for ironing (from the chart). This is expressed as  $W = P \cdot l$ , where  $W$  is work in inch-tons,  $P$  is pressure in tons, and  $l$  is length in inches. If a reducing operation accompanies ironing, then the drawing pressure should be added to the ironing pressure. If the ironing operation is done merely to correct the natural changes in wall thickness due to drawing and reduces the thickest portion near the top of the shell to equal the thinnest portion near the bottom, the average ironing pressure will equal approximately half the maximum, and the formula will be  $W = 0.5 P \cdot l$ .

Fig. 22 Chart for determining pressures required for ironing. Source: Ref 1

## Drawing of Boxlike Shells

Square or rectangular shells can be formed by redrawing circular shells when there is no flange. When flanges are required, the difficulty of producing acceptable boxlike shapes by drawing is increased. For deep-drawn square or rectangular shells (for example, where the depth is greater than either length or width), the best approach for forming a narrow flange is to allow sufficient stock and to form the flange after redrawing from a cylindrical shell.

Shallower boxlike shapes (for example, with proportions similar to the box illustrated in Fig. 23) can be drawn with a flange, which is then trimmed to the desired width. Calculations for the area of a blank used for a circular workpiece cannot be used for a square or rectangular box. These require metal in the bottom, ends, sides, and flange, as shown when a box is unfolded (flat pattern, Fig. 23). The excess metal at the corners (shaded areas, Fig. 23) is a problem.

A seamless square or rectangular shell is made by drawing metal into the corners. The metal not needed for the corners is pushed into the walls adjacent to the corner radius and into earlike extensions of the corners. The compressive stresses set up when the metal in the corners is rearranged cause the metal to be thicker in the corners than in the sidewall or in the original blank.

The more difficult draws are made more easily by using a carefully developed blank. There are methods of developing the shape at the corners of a blank for a square or rectangular shell so that there is a minimum of excess metal. However, by cropping the corners as shown in Fig. 23 and by using a blankholder, satisfactory parts can generally be made. Draw beads in the blankholding surface surrounding the die are frequently used.

## Drawing of Workpieces with Flanges

Regardless of whether the drawn workpiece is circular, rectangular, or asymmetrical, producing acceptable small-width flanges on workpieces is seldom a problem. Flanged workpieces are usually drawn in two or more operations, frequently with restriking as a final operation.

**Cylindrical workpieces** with wide flanges are troublesome to draw because of excessive wrinkling or fracturing in the sidewall due to lack of metal flow. Even though the metal is restrained by a blankholder, it is difficult to

Fig. 23 Flanged rectangular box drawn from a blank with restraint at the corners. See text for details.

obtain acceptable flatness without special procedures. Wide flanges on relatively large workpieces can be made flat by coining after drawing. Another means of dealing with wrinkling, when design permits, is to provide ribs in the flange. This controls the wrinkling by allowing space for the excess metal. Ribs are usually spaced radially around the flange, although circular, concentric ribs also are effective.

**Rectangular, boxlike workpieces** that have flanges are difficult to redraw in such a manner that the flange is unaffected in redrawing operations. Therefore, it is common practice to draw the part first to a shallower depth and with larger bottom radii than needed for shaping the final contour. The part is then reformed in a final operation.

**Asymmetrical workpieces** that have flanges are often difficult to draw, particularly when neither draw beads in the die nor ribs in the workpiece can be permitted. Under these conditions, considerable development is usually required to determine the blankholder pressure that will result in the desired metal flow without using a larger blank than necessary.

## Drawing of Hemispheres

In the drawing of a hemisphere, metal flow must be closely controlled for balance between excessive thinning in one area and wrinkling in another. In the top illustration in Fig. 24, the punch has begun to stretch the round blank, which is restrained by the blankholder, and the crown section of the hemisphere is being formed. At this stage, the crown section is subjected to biaxial tension, which results in metal thinning. With correct pressure on the blankholder, thinning is in the range of 10 to 15%. More than 15% thinning is likely to result in fracture of the crown section. In the top illustration in Fig. 24, the portion of the blank under the blankholder has not begun to move.

As the drawing operation continues, the metal begins to move from the blankholder, and a different problem develops (center illustration, Fig. 24). Here, the metal has been drawn into a partial hemisphere with unsupported metal in a tangential slope between the punch and the clamped surface. Unlike the drawing of straight-sided shapes, the wide gap (wrinkling area, Fig. 24) prevents the use of the draw ring bore as the means of forcing the metal against the punch surface; therefore, the probability of wrinkling increases. Because the metal cannot be confined between the punch and die, wrinkling is likely to occur in this area.

To prevent wrinkles, the metal must flow from the flange area and, at the same time, must be securely held in tension. This requires an additional stretching force, derived from the portion of the blank that remains clamped. The area of metal between the clamping surfaces is gradually reduced as the punch advances, but the draw radius offers some resistance because the metal

must follow a sharper bend as it moves into the die.

One means of controlling wrinkling is by the use of draw beads, as shown in the bottom illustration in Fig. 24. Another means is by a sharp draw radius. Small radii are susceptible to metal pickup and, depending on sharpness, can produce undesirable circumferential grooves in the hemisphere if the punch does not move at a steady rate.

## Reducing Drawn Shells

Necking and nosing are used for reducing the diameter of a drawn cup or shell for a part of its height.

**Necking.** By the die reduction method, the work metal is forced into compression, resulting in an increase in length and wall thickness. The thicknesses of a shell before and after necking are related by:

$$t_2 = t_1 \sqrt{\frac{d_1}{d_2}} \quad (\text{Eq 9})$$

and heights before and after necking by the formula:

$$h_2 = h_1 \sqrt{\frac{d_1}{d_2}} \quad (\text{Eq 10})$$

where  $t_1$  is the shell thickness before necking,  $t_2$  is the shell thickness in the necked area after necking,  $d_1$  is the mean diameter of the shell before necking,  $d_2$  is the mean diameter after necking,  $h_1$  is the unit of height before necking, and  $h_2$  is the unit of height after necking.

Figure 25 shows the flow of metal in a necking operation. As the metal flows, paths of least resistance are taken. Therefore, the actual values

for  $t_2$  will be less, and for  $h_2$  greater, than those calculated from Eq 9 and 10.

Necking results are uniformly better if the workpiece has been slightly cold worked. This provides added strength to resist bulging in the column section and buckling in the section being reduced. The entry angle on the necking die is important because the probability that the metal will collapse is decreased as the angle with the vertical becomes smaller. This angle should be less than  $45^\circ$  (Fig. 25). If the angle is greater than  $45^\circ$ , a series of reductions may be necessary, with localized annealing between reducing operations. With a die entry angle less than  $45^\circ$ , thin-wall tubes can be reduced as much as 15% in diameter; thick-wall tubes can be reduced as much as 20%.

**Nosing** reduces the open end of a shell by tapering or rounding the end (usually by cold reduction) and is primarily used in making ammunition. Shells are often machined before, instead of after, nosing. Shells are usually cold reduced as much as 30% of their original diameter by nosing.

**Ironing** is the intentional reduction in wall thickness of a shell by confining the metal between the punch and the die wall. When ironing occurs, the force needed to displace the punch often increases to a secondary maximum in the force-displacement curve. The second force maximum can be of such magnitude that the shell will break. However, after ironing has started and metal has been wrapped around the punch, the force is uniform and frequently less than that for redrawing operations.

Ironing is seldom used with redrawing operations unless the amount of wall thinning is relatively small, because it results in excessive die wear, causes workpiece breakage, and increases press tonnage requirements. If a shell with constant wall thickness is needed, however, it can be obtained only by ironing.

Fig. 24 Drawing of a hemisphere with and without a draw bead. See text for more information.

## Expanding Drawn Workpieces

There are several methods for expanding portions of drawn workpieces in a press. Because the wall thickness is reduced during expansion, it is not advisable to increase the diameter for ductile metal shells (such as low-carbon steel or copper) more than 30%. If a diameter increase of more than 30% is required, the operation should

Fig. 25 Flow of metal in the reduction of a drawn shell by necking. See text for details.

be done in two or more stages, with annealing between stages.

**Expanding with a Punch.** In expanding with a punch, as in Fig. 26, the portion to be expanded is first annealed. Localized annealing, instead of annealing the entire cup, helps retain strength in the remainder of the cup. Regardless of whether or not the strength is required in the finished part, maximum column strength is desirable to prevent buckling as the punch enters the cup.

After the cup has been placed in the die (Fig. 26a), the punch moves downward and expands the top of the cup (Fig. 26b). During the return stroke, the workpiece is stripped from the punch by the stripper ring and is ejected from the die by the ejection pad.

In an expanding operation of this kind, die dimensions are predetermined within reasonably close limits during the design stage. However, the possibility of later design changes must always be considered. Depending on the shape and location of the expanded section, a height reduction of the cup may occur that will require some modification of the die and punch after tryout.

**Expanding with segmented dies** is often used for forming sidewalls of drawn shells or sections of tubing. The forming segments are contracted by compression springs and expanded radially by a tapered punch. The die is made of two or more segments held apart by compression springs. As the press ram descends, cams move the die segments together. The punch then moves the inner segments outward, thus forming the contours in the sidewall. The presence of gaps between the forming segments is one of the disadvantages of this method and is the reason an alternative method, such as rubber-pad forming, is sometimes selected.

## Deep Drawing of Pressure Vessels

Various grades of steel, many of them high-strength alloys, are deep drawn to make cylinders for compressed gases. Joints (when they are made) are around the girth of the vessel, rather than longitudinal. The integrity of the vessel is critical. Commercial-quality hot-rolled steels in the as-rolled condition are generally used. The work metal is usually induction heated or induction annealed to minimize scale.

For propane gas, pressure tanks must have high strength at minimum weight. In one application, the weight of such a tank was reduced from 59 to 32 kg (130 to 70 lb) by changing from 1025 steel to a high-manganese deep-drawing steel (Fe-0.2C-1.6Mn-0.025P-0.3S). Before drawing, the high-manganese steel had a minimum yield strength of 345 MPa (50 ksi) and a minimum tensile strength of 485 MPa (70 ksi).

Bottles for dispensing small quantities of liquefied gases or gases under high pressure are commonly made of drawing-quality low-carbon steel to take advantage of the improved mechanical properties produced by deep draw-

ing. The bottles range in size from 12.7 mm ( $\frac{1}{2}$  in.) in diameter by 32 mm ( $\frac{1\frac{1}{4}}$  in.) long to 38 mm ( $1\frac{1}{2}$  in.) in diameter by 150 mm (6 in.) long.

## Deep Drawing Using Fluid-Forming Presses

Fluid forming (also termed hydroforming) is a deep-drawing process that uses only one solid die half. Forming pressure is applied by the action of hydraulic fluid against a flexible membrane, which forces the blank to assume the shape of the rigid tool.

Fluid forming can be used for deep drawing and, in fact, offers advantages over other forming methods. One of these is that the draw radius can be varied by changing the pressure of the hydraulic fluid during the forming operation. This makes it possible to have, for example, a large draw radius at the start of the operation that decreases as the draw continues. Thus, reductions of up to 70% in a single pass are possible when drawing cylindrical cups; for rectangular-shaped parts, a height of six to eight times the corner radius can be obtained in a single operation.

Presses for fluid forming sometimes use a telescoping ram system. Figure 27 shows a schematic of one type of press used for fluid forming. Figure 28 illustrates the deep-drawing process on a press of this type. More information on fluid-forming equipment and processes is

available in the article "Rubber-Pad Forming and Hydroforming" in this Volume.

## Ejection of Workpieces

In drawing operations, the drawn workpiece may adhere to either the punch or the die. Adherence is increased by depth of draw, straightness of workpiece walls, and viscosity of lubricant. The simplest means of ejecting a small workpiece is by compressed air through jets in the punch or the die. Timed air blast is widely used for ejecting relatively small workpieces, for example, where cup diameter is no greater than 102 to 127 mm (4 to 5 in.). In some production drawing operations, the workpiece is ejected by compressed air, and another timed blast of air from the side removes the piece by sending it down a chute or into a container. However, for larger workpieces or for those that are deep, some other means of ejection is required.

Mechanical methods of ejection include:

- Edge stripping by means of a lip on the draw ring (Fig. 29a) or by a spring-actuated stripper (Fig. 29b)
- The use of a blankholder in combination with an upper ejector (Fig. 30)
- The use of a lower ejector in combination with an upper stripper ring (Fig. 31)

(a)

(b)

**Fig. 26** Expansion of the mouth of a drawn shell with a punch

**Fig. 27** Schematic of one type of fluid-forming press used for deep drawing

Numerous other mechanical methods using cams or links have been devised to meet specific requirements. These methods are usually modifications of those described previously. For example, thin shells are sometimes stripped from punches near the top of the press stroke by a cam-actuated rod that extends through the punch. This

method is often used to avoid damage to the open end of the shell, which can occur when the piece is ejected by other methods. The major factors influencing the method of ejection are workpiece design (especially the presence or absence of a flange), work metal composition and thickness, and the type of equipment available.

**Fig. 28** Deep-drawing process using the fluid-forming press shown in Fig. 27. (a) The blank is placed on the blank holder. (b) The outer ram moves upward, carrying the blank. (c) Oil is pumped into the inner ram system, pressing the punch upward. (d) Outer ram is returned to its initial position, and the punch is retracted to allow removal of the formed part.

**Fig. 29** Setups showing two methods of ejecting a drawn workpiece through the bottom of the press by edge stripping

**Fig. 30** Use of a blankholder and ejector for stripping of a drawn workpiece from inverted dies

## Trimming

Trimming in a lathe (using a cutting tool), roll trimming in a lathe, rotary shearing, die trimming (regular and pinch), and trimming on special machines are the methods most commonly used for trimming drawn workpieces.

**Methods for Specific Shapes.** Cylindrical workpieces, such as the one shown in Fig. 32a, can be trimmed by at least four different methods:

- In a lathe, with a cutting tool, but production cost is high
- By roll trimming in a lathe or in a rotary shear. Production cost is lower than that for trimming with a cutting tool, but the finish of a rolled edge is poor and maintenance cost of the rolls is high.
- By pinch trimming in the press at the bottom of the drawing stroke. This involves almost no increase in production cost but requires a more expensive die. This method produces a thinned edge at the trim line, which may be unacceptable.
- In a shimmy die or trimming machine, but production quantities must be high to warrant the investment

Cylindrical workpieces with flanges, such as the one shown in Fig. 32b, can also be trimmed in a lathe, although shapes such as this are ideal for trimming in a die and can be die trimmed for approximately 5% of the cost of trimming in a lathe. Rotary shearing can also be used for trimming circular drawn parts with flanges if the dimensional tolerance is 0.76 mm (0.030 in.) or more. Drawn workpieces with an irregular trim line, as in Fig. 32c, can be trimmed in a die for

**Fig. 31** Setup in which drawn workpiece is lifted from the die by an ejector and is stripped off the punch by a fixed stripper ring

low-production requirements, or with a shimmy die or trimming machine for high-production requirements. The cost of a trimming die is approximately half that for a special trimmer (excluding the cost of the original machine). However, the trimming cost per piece with the special trimmer will be only approximately half the per-piece cost with multiple dies, and the trimmed edges will be better.

Flanged workpieces, such as the one shown in Fig. 32d, can be trimmed in a die for 5% of the cost of trimming in a rotary shear. In low production, drawn workpieces of such a shape are frequently trimmed in a nibbler and filed to conform to a template. This means of trimming costs up to 60 times as much as die trimming.

## Developed Blanks versus Final Trimming

The most important factor that influences a choice between using a developed blank or a final trimming operation is whether or not the shape of the drawn edge is acceptable. A semi-developed blank is sometimes necessary to draw an acceptable part, and the edge must be trimmed to meet dimensional tolerances.

The next consideration is the cost of blanking versus final trimming. This would include the adaptability of the process to the available equipment, based on expected production requirements. The principal advantage of a developed blank is that strip or coiled work metal can be used. The use of strip eliminates the need for shearing the work metal to a rough-blank shape, as is sometimes required when final trimming is used. The developed-blank approach is usually more economical than final trimming because a blanking die is frequently less expensive than a final-trimming die.

When using developed blanks, the draw dies are made, and several blanks are drawn to select the optimal developed shape before the blanking die is made. This causes a delay in placing the draw die into production. However, with proper planning and scheduling, this should not be a problem. Another disadvantage of developed blanks occurs when variations in work metal properties and thickness are sufficient to affect the uniformity of the drawn workpiece. Under these conditions, closer tolerances are obtained by final trimming. It is possible to develop blank contours accurately enough so that the outline of the drawn part is within tolerance, thus avoiding a final-trimming operation.

## Cleaning of Workpieces

In general, the more effective the lubricant, the more difficult it is to remove. Therefore, an overly effective drawing lubricant should be avoided.

The cleaning method depends on the work metal composition, the lubricant, the degree of

cleanliness required, workpiece shape, and sometimes the length of time between application of lubricant and its removal. Some metals will be attacked by cleaners that are not harmful to others. For example, strong alkaline cleaners are suitable for cleaning steel and many other metals, but they are likely to attack aluminum alloys. Detailed information is available in the articles on the surface engineering of specific metals in *Surface Engineering*, Volume 5, *ASM Handbook*, 1994.

Unpigmented oils and greases can be removed from steel workpieces by several simple shop methods, including alkaline dipping, emulsion cleaning, and cold solvent dipping. These methods are usually sufficient for in-process cleaning. However, if the workpieces are to be painted, a more thorough cleaning by emulsion spray or vapor degreasing is required. For plating, electrolytic cleaning plus etching in acid (immediately prior to plating) is required. These latter methods usually follow a rough cleaning operation.

Pigmented drawing lubricants and waxes greatly increase cleaning problems. At a minimum, in-process cleaning usually requires slushing in a hot emulsion or vapor degreasing. If the lubricant is not removed for several days after application, soaking in a hot alkaline cleaner or an emulsion cleaner may be required. Particularly for complex workpiece shapes, some hand or power brush scrubbing may be needed. If the workpieces are to be painted or plated, additional cleaning will be required, as described previously. Detailed information on the choice of

Fig. 32 Typical trim lines on drawn parts. See text for details.

cleaning method is available in the article "Classification and Selection of Cleaning Processes" in *Surface Engineering*, Volume 5, *ASM Handbook*, 1994.

## Dimensional Accuracy

Dimensional accuracy in deep drawing is affected by the variation in work metal thickness, variation in work metal condition (chiefly hardness), drawing technique (particularly the number of operations), accuracy of the tools, rate of tool wear, and press condition. Control of dimensions begins with the purchase of sheet to closer-than-commercial thickness tolerance, which adds substantially to the cost. Close control of sheet hardness also costs more. In-process annealing may be required to minimize spring-back or warpage; it will not be needed if tolerances are more liberal. Annealing, handling, and cleaning operations are costly.

As tolerances become closer, it is often necessary to add more die stations to minimize the amount of drawing in any one station. Close tolerances may demand restriking operations that would not be necessary for parts with more liberal tolerances. Additional operations increase tool costs and decrease productivity, thus increasing the cost per piece.

The initial cost of tools increases as tolerances become closer because of greater cost for precision machining and grinding or more costly tool materials. In addition, tool life before reconditioning and total tool life decrease as tolerances become closer. Maintenance costs and downtime of presses are also greater.

When required, extremely close tolerances can be maintained on some parts (Fig. 33).

Fig. 33 Variation in bearing pathway diameter of a needle bearing cup drawn using high-speed tool steel and carbide dies

In most deep drawing, the accuracy shown in Fig. 33 is either impossible or impractical. The more usual practice when dimensional accuracy is important is to check critical dimensions at specified intervals during a production run and to plot the variation. Data from this method of quality control show the capabilities of the process under shop conditions and the magnitude of drift during a production run. When results (either initially or during a run) are unacceptable, one or more of the controls discussed at the beginning of this section can be applied.

## Safety

Deep drawing, like other press operations, involves potential hazards to operators and other personnel in the work area. No press, die, or auxiliary equipment can be considered ready for

operation until these hazards are eliminated by the installation of necessary safety devices. Operators should be properly instructed in safe operation of equipment.

# Stretch Forming

Revised by Mahmoud Y. Demeri, FormSys, Inc.

**STRETCH FORMING** is the forming of sheet, bars, and rolled or extruded sections over a die or form block of the required shape while the workpiece is held in tension. The workpiece is usually gripped by mechanical jaws on each end and then stretched and simultaneously bent over a die containing the desired shape. The work metal is often stretched just beyond its yield point (generally 2 to 4% total elongation) to retain permanently the contour of the form block. Controlling the amount of stretching is important to avoid splitting. The combination of stretching and bending reduces springback in the formed part. Stretch forming cannot produce parts with sharp contours or depressions. It is primarily used to make aircraft skin panels, window frames, and automotive door panels.

The four methods of stretch forming are:

- Stretch draw forming (Fig. 1a and b)
- Stretch wrapping, also called rotary stretch forming (Fig. 1c)
- Compression forming (Fig. 1d)
- Radial draw forming (Fig. 1e)

These methods are discussed separately in subsequent sections of this article.

## Applicability

Almost any shape that can be produced by other sheet-forming methods can be produced by stretch forming. Drawn shapes that involve metal flow, particularly straight cylindrical shells, and details that result from such compression operations as coining and embossing cannot be made. However, some embossing is done by the mating-die method of stretch draw forming (Fig. 1b).

Stretch forming is used to form aerospace parts from steel, nickel, aluminum, and titanium alloys and other heat-resistant and refractory metals. Some of these parts are difficult or impossible to form by other methods, for example, the titanium alloy gas-turbine ring shown in Fig. 2. The procedure for making such a ring is described in Example 5 in this article.

Stretch forming is also used to shape automotive body panels, both inner and outer, and frame members that could be formed by other processes but at higher cost. An example is the automobile roof shown in Fig. 3, which was stretch draw formed using a blank that weighed

2.9 kg (6.4 lb) less than would have been needed for a conventional press-forming process. Architectural shapes and aerospace forms that call for compound curves, reverse bends, twists, and bends in two or more planes are also produced by stretch forming.

**Advantages.** Stretch forming has the following advantages over conventional press-forming methods:

- Approximately 70% less force is needed than that required for conventional press forming.
- Stretch forming can reduce material costs by as much as 15%. Although allowance must be made on the stock for gripping, it is gripped on two ends only. The allowance for trimming is usually less than that in conventional press forming.
- Because stretch forming is done on the entire area of the workpiece, there is little likelihood of buckles and wrinkles. Tensile strength is increased uniformly by approximately 10%.
- Hardness is increased by approximately 2%.
- Springback is greatly reduced. There is some springback, but it is easily controlled by overforming.

**Fig. 1** Fundamentals of the techniques involved in the four methods of stretch forming

- Residual stresses are low in stretch-formed parts.
- Form blocks are made of inexpensive materials, such as wood, plastic, cast iron, or low-carbon steel, and are approximately one-third the cost of conventional forming dies. If the workpiece is formed hot, the dies must be able to withstand the forming temperature. However, most stretch forming is done at room temperature.
- Changeover is simple. Only one form block and two sets of grippers are involved. To make the same part from a different metal or another stock thickness, the same form block and grippers are used, but the tension of the stretch mechanism is adjusted.

**Limitations.** Stretch forming is subject to the following limitations:

- It is seldom suited to progressive or transfer operations.
- It is limited in its ability to form sharp contours and reentrant angles. It is at its best in forming shallow or nearly flat contours.
- If the piece is not pinched between mating dies, there is no opportunity to coin out or iron out slight irregularities in the surface of the metal.
- In some applications, especially in stretch wrapping, the process is slower than competitive processes, and it is not suited to high-volume production. However, stretch draw forming with mating dies can be done as rapidly and automatically as conventional press operations. In fact, punch presses are used with dies incorporating draw beads or other means of gripping the blank in order to perform some stretch-forming operations.
- Metals with yield strength and tensile strength very nearly the same, such as titanium, necessitate the use of automatic equipment for determining the amount of strain for uniform results.
- Optimal results are achieved with rectangular blanks. The aircraft industry uses trapezoidal blanks but gives greater attention to each piece than is warranted in high-volume production.
- Deep forming in the direction of the free edges is not practical.

## Machines and Accessories

Stretch wrapping, compression forming, and radial draw forming use rotary tables (some with sliding leaves) for mounting the form blocks, a ram gripping and tensioning or wiping device, and a mechanically or hydraulically actuated table gripper (Fig. 4). Machines used for these operations have capacities to 8900 kN (1000 tonf).
